Electromyography and nerve conduction studies of patients with peripheral neuropathy secondary to thallium intoxication demonstrate diffuse axonal degeneration of sensory and motor fibers, particularly in the distal lower extremities. Although abnormalities in nerve conduction studies, visual evoked potentials, and brainstem auditory evoked potentials improve along with symptoms, abnormalities may persist at least several years after cessation of exposure.[99] Manifestations of these electrophysiological abnormalities include marked reduction in CMAP amplitudes with mild slowing of motor and sensory nerve conduction velocity and relatively normal distal latencies, particularly in the lower extremities.[124] In an adolescent with severe peripheral neuropathy from thallium intoxication, weakness and sensory disturbances persisted for years after poisoning, primarily in his feet.[95] Electrodiagnostic studies demonstrated bilateral improvement in voluntary activity of distal lower limb muscles along with increases in the response amplitudes of median and sural nerves when compared with earlier studies. An electrophysiological investigation of a thallium-intoxicated patient with optic atrophy revealed a conduction block of the retinal nerve fibers (reduced visual evoked potentials) and lesions near the retinal bipolar cells (diminished amplitude on multifocal electroretinography).[125]

Neuropsychological Testing

Case reports suggest thallium intoxication produces temporal lobe dysfunction on neuropsychological testing (i.e., deficits in memory recall, reversed digit span, memory recognition, similarities, proverb reasoning, verbal fluency) correlating with hypointense lesions in T1-weighted images and hyperintense lesions in T2-weighted images of the corpus striatum on the brain MRI.[126] Slow improvement occurred over 1 year including resolution of the lesions. These patients also display anxiety, depression, and emotional lability.

TABLE 30.2. Regulations and guidelines for exposure to thallium. (Adapted from Lauwerys and Hoet).[127]

Exposure Limit	Value
OSHA	
PEL–TWA[a] (8-hour)	
Soluble Tl	100 μg/m^3
NIOSH	
REL–TWA (10-hour)	100 μg/m^3
IDLH	15,000 μg/m^3[b]
ACGIH	
TLV–TWA (8-hour, with skin notation)	20 μg/m^3
US EPA	
RfD (chronic oral exposure)	NA
MCL	None

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfD = reference dose; TLV = threshold limit value; TWA = time-weighted average; US EPA = US Environmental Protection Agency; NA = not available.
[a] As metallic Tl; [b]soluble thallium compounds only.

HEALTH SURVEILLANCE

The US PEL–TWA for thallium and soluble thallium salts is 0.1 mg Tl/m^3 with a skin notation. Table 30.2 outlines the regulations and guidelines for thallium and thallium compounds. In a study of 128 cement production workers exposed to thallium, spot urine samples contained Tl concentrations ranging from <0.3 (LOD) to 6.3 μg/g creatinine; history and physical examination of these workers did not detect any clinical features characteristic of thallium intoxication.[106] Urinary Tl concentrations of 100 μg/L in asymptomatic workers roughly correlate to workplace exposures at the threshold limit value of 0.1 mg Tl/m^3 based on a study of workers manufacturing thallium-containing seawater batteries.[105] The recommended action level for occupational Tl exposure was 50 μg/L; however, there are few data to substantiate this value.[127]

TREATMENT

Decontamination

The usual gastrointestinal decontamination measures (activated charcoal, lavage) may be used within the first 1–2 hours after exposure; however, the delayed presentation of thallium intoxication usually results in the arrival at health care facilities long after decontamination measures would be effective. *In vitro* studies suggest activated charcoal binds thallium, and thallium undergoes hepatic recirculation; hence, at least a single dose probably is beneficial. A cathartic may be necessary for severe thallium poisoning when constipation complicates the administration of activated charcoal and/or Prussian blue. The presence of radiopaque material in the gastrointestinal tract suggests the need for whole bowel irrigation; however, there are insufficient clinical data to guide the use of this modality. Because of potential skin absorption, clothing in direct contact with thallium compounds should be removed and the skin washed with soap and water.

Enhancement of Elimination

Prussian Blue

Prussian blue is the crystal blue lattice of soluble potassium ferric hexacyanoferrate; this compound reduces thallium gastrointestinal absorption and increases fecal excretion by exchanging thallium for potassium.[128] This exchange disrupts the enterohepatic circulation of thallium, creating a gradient between the intestinal tract and the blood. The gradient favors the movement of thallium into the intestines. In animal studies, the administration of Prussian blue reduced Tl half-life from 4 days to 2 days.[129] The affinity of Prussian blue for thallium depends on the particle size and the form (i.e., colloidal or soluble form vs. non-colloidal or insoluble form). Small particle size and high solubility enhance the affinity of Prussian blue for thallium;[130] however, these characteristics vary between different batches of Prussian blue. The administration of this compound causes few side effects except constipation as a result of the poor absorption of the Prussian blue–thallium complex from the gastrointestinal tract. Experimental studies in rats indicate Prussian blue reduces brain thallium concentrations and overall mortality during acute thallium intoxication.[131,132] This compound is commercially available in Europe and the United States as insoluble Radiogardase™ (HEYL Chemisch-pharmazeutische Fabrik Gmb H & Co., Berlin); pathology labs use Prussian blue for nonmedicinal purposes. Although there are insufficient data to determine if the insoluble form of Prussian blue is as effective as the soluble form, the insoluble form of Prussian blue (Radiogardase™) is approved by the US FDA for the treatment of thallium poisoning.[128] Prussian blue (Radiogardase™) is available through the Radiation Emergency Assistance Center in Oakridge, Tennessee (www.orau.gov/reacts/prussian.htm) or the US FDA. Prussian blue is 35–40% cyanide by weight; however, *in vitro* studies suggest long-term storage over 10 years does not increase cyanide release despite some water loss.[133]

The capacity of Prussian blue to improve clinical outcomes during thallium intoxication remains unproven in the absence of controlled human trials.[60] Several authors recommend the use of Prussian blue in thallium poisoning, particularly when administered *early* in the clinical course.[96] The usual daily dose is 250 mg colloidal (soluble) Prussian blue/kg divided into four oral administrations. The recommended adult dose of insoluble Prussian blue (Radiogardase™) is 3 g orally three times daily. The pediatric dose for 2–12-year-old children is 1 g three times daily. A mild cathartic (e.g., 50 mL 15% mannitol containing the Prussian blue dose or 50–100 mL 15% Sorbitol) helps prevent constipation. An alternative to a cathartic is a high fiber diet should be added to each dose to prevent constipation. Inadequate data are available to determine the optimum duration of Prussian blue treatment.

Severe poisoning with protracted vomiting may require the placement of a duodenal tube to administer the Prussian blue.[134] The administration of 50 mg Prussian blue/kg produced a statistically significant increase in the 5-day survival of mice receiving 70–85 mg Tl/kg; however, the addition of 200 mg *N*-acetylcysteine/kg did not affect 5-day survival.[135] The patient should be monitored for the development of hyperkalemia. *In vitro* studies suggest thallium excretion increases in an alkaline environment,[136] but no human studies are available to confirm the efficacy of alkalinization.

Multi-dose Activated Charcoal (MDAC)

The administration of serial doses of activated charcoal is an alternative to Prussian blue when the latter is unavailable; however, human data on the clinical efficacy of MDAC during thallium intoxication are limited.[88] *In vitro* and rodent studies suggest activated charcoal effectively binds thallium ions;[137,138] however, inadequate data are available to assess the efficacy of serial doses of activated charcoal or the combination of MDAC and Prussian blue on the outcome of thallium intoxication.

Extracorporeal Methods

Although thallium is a small molecule with no significant protein binding, the large volume of distribution and intracellular distribution of thallium theoretically limit the effectiveness of these methods. Forced diuresis increases thallium excretion by 60% in animal models;[139] however, this method is limited by the relatively small amount of thallium cleared by the kidney after a Tl overdose. There are limited data on the effect of hemodialysis on thallium clearance. In a severe case of thallium poisoning (serum thallium = 5,240 μg/L ~ 4 hours post-ingestion), the reported Tl clearance rate from the blood ranged from 96–150 mL/minute.[140] A case report of thallium poisoning demonstrated that hemofiltration did not remove clinically significant amounts of thallium.[91] Hemoperfusion may enhance thallium clearance when combined with hemodialysis.

In severe poisoning, the early use (i.e., within the first day) of the combination of hemodialysis or hemoperfusion is a therapeutic option, although the clinical effectiveness of this treatment remains unproven. In a 32-year-old woman who was normotensive 7 hours after the ingestion of 100 mg thallium sulfate, the thallium clearance was 150 mL/minute at a blood flow rate of 200 mL/minute. The estimated amount eliminated by the combination of 4 hours of hemodialysis and hemoperfusion was only ~7% of the estimated ingested dose.[141] The estimated mean thallium clearance from hemoperfusion and hemodialysis was 139 mL/minute and 49 mL/minute, respectively. In a patient hypotensive from severe thallium intoxication, the thallium clearance values during two different times were 50.2 and 60.4 mL/minute at a blood flow rate of 100 mL/minute.[51] The use of hemodialysis for 120 hours eliminated 143 mg (~7%) of an estimated 2 g-thallium overdose by a 56-year-old woman.[142] During the first few days following a thallium overdose, thallium concentrations are relatively high; therefore, measures to enhance elimination should be initiated as soon as possible.

Despite the relatively low dialyzability of thallium and limited clinical data to support the use of dialysis, the Extracorporeal Treatments in Poisoning (EXTRIP) workgroup recommended the use of hemodialysis in severe thallium poisoning.[143] Indications included history or clinical features suggestive of thallium intoxication or serum thallium concentration of >1 mg/L. Treatment recommendations included initiating hemodialysis as soon as possible (i.e., within 24–48 hours) and continuing hemodialysis until the serum Tl concentration is <0.1 mg/L or a minimal duration of 72 hours.

Potassium Chloride

In general, the potassium concentration should be kept in the normal range without additional supplementation. The role of potassium *alone* in the treatment of thallium poisoning is controversial. Potassium may inhibit the resorption of thallium from the renal tubule and displace thallium from intracellular stores. Some animal studies suggest potassium supplementation increases the excretion of thallium; however, the amount excreted is relatively small.[73] Potassium chloride supplementation (40–65 mEq/day in adults) and diuresis increase thallium excretion, but the redistribution of thallium to the brain may enhance toxicity. Case reports have not documented the efficacy of this regimen. The combination of *peritoneal dialysis* and potassium chloride diuresis removed only 30–35 mg of thallium (6% of the estimated dose) daily.[144] Consequently, potassium-enhanced diuresis has very limited use in thallium intoxication; other measures (e.g., activated charcoal, hemodialysis, charcoal hemoperfusion, Prussian blue) are better techniques to enhance thallium elimination.[145,146]

Chelating Agents

Thallium does not respond to traditional chelation therapy in the absence of clinical data to support the use of chelating agents (diethyldithiocarbamate, $CaNa_2$ EDTA, BAL, penicillamine). Diethyldithiocarbamate causes redistribution of thallium to the central nervous system, resulting in a worsening of neurological symptoms.[147] Case reports on the effectiveness of DMSA to remove thallium are limited and conflicting; there are inadequate experimental data to determine the efficacy of chelating agents.[131] The effectiveness of combined therapy (e.g., D-penicillamine, Prussian blue) as a means to increase Tl removal from critical target organs without redistribution of thallium following the use of chelating agents remains to be confirmed in human studies.[148]

Supplemental Care

Severe stomatitis may develop following thallium poisoning; therefore, mouthwashes and gargles are preferable to tooth brushing.[149]

Chapter 31

TIN

METALLIC AND INORGANIC TIN

HISTORY

Tin smelting dates back to the Neolithic age. Along with copper and gold, tin has been used in metallurgy for over 5,000 years. Bronze, the tin–copper alloy, was invented ~2,500 BC.[1] The Romans coated metal with tin. Initially, tin was the main constituent of food containers because the storage of food and drinks in these vessels did not alter flavor or taste. During the Napoleonic wars, the preservation of foods by sealing them in tin cans was developed; by the middle of the 19th century, the practice of packaging food in tin cans was widespread in the United States. Medicinal use of tin and inorganic tin compounds (stannous chloride, tin oxide) began several centuries ago with the oral administration of these relatively insoluble compounds as anthelmintics.[2] Tin compounds were believed to possess anti-staphylococcal properties because French tin miners in Beauve seldom developed furuncles.[3] During the 1940s, a benign pneumoconiosis was attributed to workers chronically inhaling dusts and fumes from processes involving the bagging and smelting of tin oxide.[4]

PHYSIOCHEMICAL PROPERTIES

Tin is a member of Group 14 (Group IVA germanium, lead) of the periodic table that forms two primary oxidative states, stannous (Sn^{2+}) and stannic (Sn^{4+}). At pH >6, stannous compounds are strong reducing agents. Stannous chloride and stannous sulfate are strongly acidic, whereas potassium and sodium stannate are strongly alkaline; the irritant properties of these compounds are sufficient to cause skin and mucous membrane irritation. In nuclear medicine, these compounds function as reducing agents for ^{99m}technetium.[5] Stannous compounds easily oxidize at pH >6. Tin forms a highly toxic hydride, stannane (SnH_4). Table 31.1 lists the identifying information and physical properties of tin and common tin compounds. Elemental tin is a lustrous white, soft, odorless, malleable metal with very high density (i.e., 7.3). This metal has a highly crystalline structure that exists in two allotropic forms under normal pressures depending on temperature. Below ~13°C, tin appears as a gray material with a cubic structure, whereas above this temperature, tin is a white material with a tetragonal structure. At 200°C, tin becomes brittle, and below −40°C, tin crumbles into a gray amorphous powder. Tin exists in the environment primarily as colloidal complexes rather than ionized forms; typically, a transparent film of SnO_2 covers elemental tin. The affinity of divalent and tetravalent inorganic tin for nitrogen and sulfur ligands is low, limiting the toxicity of inorganic tin.

TABLE 31.1. Identifying information and physical properties of tin and inorganic tin compounds. (Adapted from ATSDR).[6]

Physical Characteristic	Tin	Tin Chloride	Tin Oxide	Tin Fluoride
Formula	Sn	$SnCl_2$	SnO_2	SnF_2
Synonym	Metallic tin, silver matt powder	Stannous chloride, tin dichloride	Stannic oxide, tin oxide, stannic anhydride	Stannous fluoride
CAS RN	7440-31-5	7772-99-8	18282-10-5	7783-47-3
Valence	0	+2	+4	+2
Molecular weight (g/mol)	118.69	189.60	150.71	156.71
Color	Silver–White	White	White	White
Physical state	Solid	Solid	Solid	Solid
Melting point (°C)	231.9	246	1,630	213
Density (g/mL, 20°C)	5.769 (gray) 7.265 (white)	3.9	6.95	4.57 (25°C)
Odor	Odorless	Odorless	Odorless	Odorless
Water solubility (g/100g)	Insoluble	90 (20°C)	Insoluble	30 (20°C)
Vapor pressure (mmHg)	8×10^{-3} (1,224°C)	25 (427.9°C)	~0	NA

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number; NA = not available.

EXPOSURE

Production Processes

Tin comprises ~0.0006% of the earth's crust; the major producers of tin include Indonesia, China, and Peru. Although nine minerals contain tin, the only commercially important tin ore is cassiterite (~75% tin as SnO_2).[6] Tin ores contain a variety of metal contaminants including antimony, arsenic, bismuth, cadmium, cobalt, copper, iron, lead, nickel, sulfur, tungsten, and zinc. Prior to smelting, gravity or magnetic separation processes concentrate tin. The smelting process is the primary source of exposure to dusts and fumes of tin oxide.[1] Imports or recovery of tin from scrap materials are the main sources of tin consumed in the United States.

Uses

In tin smelters, feed mixing during sintering and reduction in blast furnaces convert ores to an impure alloy of tin and lead; dry refining prior to electrolytic separation yields pure tin as a cathode deposit. Workers at these smelters are potentially exposed to a variety of substances including antimony, arsenic, cadmium, lead, ^{210}polonium, and sulfur dioxide. Mortality studies at these facilities have not detected a significant increase in lung cancer in the workers.[7] The principal use of tin is in the production of containers for food and aerosols. Stannous and stannate compounds are used for electroplating. Tin is a component of solder (lead/tin alloy) and coating for copper wire. Tin alloys include brass, pewter (91% tin, 7% antimony, 2% copper), bronze (copper/tin), dental material (silver/tin/mercury), aircraft components (titanium/tin), and nuclear reactor parts (zirconium/tin).[6] Inorganic tin compounds provide strength to glass and glass coatings, act as catalysts and stabilizers during PVC production, and are involved in the formulation of perfumes, soaps, fingernail polish, and colors. Stannous fluoride, stannous pyrophosphate, stannous hexafluorozirconate, and pentafluorostannite are toothpaste additives for the prevention of cavities. Tin oxide is a small portion of the sintered alloy, indium-tin oxide, used for transparent conductive films on liquid-crystal and plasma displays. A tin plate is a small gauge, steel strip, or sheet coated with pure tin that lines ~80 billion food cans yearly; most of these containers now have lacquered linings.[8]

Sources

For the general population, the diet accounts for >99% of tin exposure with the remainder resulting from the inhalation of tin in ambient air based on analyses of balance studies from the 1950s and 1960s.[9,10]

Air

Anthropogenic and natural sources contribute about equal amounts of tin to the atmosphere. Release of tin into air results from natural (e.g., dust from windstorms, human activities) and anthropogenic (e.g., smelting, refining, coal-burning power plants) sources. Fly ash from coal-burning power plants contains 7–19 μg Sn/g.[11] The concentration of tin in ambient air is usually

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

low. Elemental tin is infrequently detected in ambient air, except near-point sources. Tin appears in the atmosphere in the form of particulates with the tin concentration generally <0.1 μg Sn/m^3 based on data collected before 1970.[6, 12]

Soil

The average concentration of tin in the earth's crust is about 2–3 ppm.[6] Most of the deposition of tin occurs in landfills and, to a lesser extent, in sewage sludge and fly ash. The mean tin concentration in US soil is ~0.9 mg/kg soil with a range up to 200 mg/kg in areas without tin deposits and up to 1,000 mg/kg in areas with large tin deposits.[13]

Water

Releases of inorganic tin into water result from industrial production; natural waters contain only trace amounts of tin. The concentration of tin in seawater was 0.2–3 μg/L; the mean tin concentration in surface water in Maine was 0.038 μg/L.[14]

Diet

Food is the primary source of tin exposure secondary to the use of tin-lined food containers; the amount of tin consumed daily depends on the portions of fresh and canned foods in the diet. Estimates of the daily intake of tin range from 1 mg (diets consisting mainly of fresh meats, vegetables, and cereals) to 38 mg (diets with high proportion of canned foods) in the older medical literature using different analytical and study methods.[9,15] The estimated daily tin intake in the United States during the 1980s was ~4 mg.[16] Later estimates of daily tin intake were up to an order of magnitude lower depending on the use of tin containers. The estimated mean daily Sn intake based on analysis of a market basket representative of the Northern Italian diet was 1.57 mg with a range of 0.01–4.44 mg.[17] Using duplicate diet samples over 24 hours, the median daily tin intake in 95 Japanese adults was 5.6 μg with a 75% of 15.3 μg and a maximum of 2,291 μg as measured by ICP/MS.[18] In a Japanese study of 296 preschool children aged 3–6 years, the median daily dietary intake of tin was 4.2 μg with a range of 0.4–>3 μg depending primarily on the amount of canned foods in the diet.[19] Although the median daily tin intake differed significantly between canned food consumers (GM = 30.2 μg) and non-consumers (GM = 3.3 μg), urinary tin concentrations between the two groups were similar as measured by inductively coupled plasma/mass spectrometry (ICP/MS). The mean estimated daily tin intake in the French diet was 2.32 mg as measured by duplicate diet samples and ICP/MS.[20]

Tin concentrations in fresh cereals, meats, and vegetables typically range from 0.1–1.0 mg/kg (ppm) depending on a variety of factors including pH, valence, solubility, adsorption to surrounding material, and the presence of complexation; however, tin concentrations up to 500 mg/kg may occur in food stored in unlacquered tin containers.[13,21] In a market basket study representative of the Northern Italian diet, cereals and tubers accounted for an estimated 97% of the daily tin exposure.[17] Tin concentrations of fruits and fruit juices, nuts, dairy products, fish, poultry, eggs, and beverages not packaged in metal cans are generally <2 mg/kg.[6] The inner surface of most cans now contains a protective lacquer coating rather than tin to reduce the corrosive effects of acidic foods. Dissolution of unlacquered tin by acidic foods can increase tin concentrations to by >200 mg/kg.[22] Foods from cans with lacquered inner coatings usually contain tin concentrations of <12–25 mg/kg.[9]

ENVIRONMENTAL FATE

Air

The deposition of metallic tin occurs by gravitational settling; washout mechanisms are relatively unimportant because the vapor pressure of tin is negligible. Theoretically, airborne particles of tin may travel long distances before deposition depending on a variety of physical and environmental factors including the type of emitting source, size, density, degradation during transport, adsorption processes, and meteorological conditions.[23]

Soil

Tin is relatively immobile in the soil as a result of adsorption to soils.

Water

Tin exists in water as stannous (Sn^{2+}) and stannic (Sn^{4+}) ions. Elemental tin is nondegradable, but this metal undergoes ligand exchange, oxidation–reduction, and precipitation reactions. In anaerobic (reducing) environments, tin occurs primarily as stannous tin; however, Sn^{4+} is more stable in the environment than Sn^{2+}. The presence of alkaline conditions encourages the formation of SnS and $Sn(OH)_2$. Methylation of inorganic tin by microorganisms can transform tin into organometallic forms,[24] but the biomethylation of inorganic tin

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

probably accounts only for small amounts of organic tin in the environment compared with anthropogenic sources.[25] In extremely anaerobic conditions, microalgae can convert inorganic tin to stannane (SnH_4).[26] *In vitro* studies suggest inorganic tin may bioconcentrate up to several thousand folds in invertebrates and fish.[6]

DOSE EFFECT

Adverse gastrointestinal effects may occur following ingestion of inorganic tin at concentrations of ≥700 ppm; case reports and volunteer studies indicate elemental tin concentrations of 1,400 mg Sn/L produce acute gastrointestinal symptoms.[27] Typically, tin concentrations of <700 mg Sn/L do not produce gastrointestinal effects depending on the amount of liquid ingested; however, the ingestion of canned tomato juice containing 477 mg Sn/L was associated with 113 cases of gastroenteritis.[28] Other studies did not detect adverse gastrointestinal effects at tin concentrations exceeding 700 ppm.[8] There is little evidence that the consumption of foods containing inorganic tin up to 200 ppm causes clinically significant acute adverse gastrointestinal effects.[8]

TOXICOKINETICS

Absorption

Although human data are limited, experimental studies suggest the lungs and gastrointestinal tract absorb inorganic tin poorly. In a balance study of eight volunteers receiving diets with low (0.11 mg/day) and high (~50 mg stannous chloride) tin content, the average tin absorption was 50% and 3%, respectively.[29] Animal studies indicate ~1–5% of an inorganic tin dose is absorbed by the gastrointestinal tract.[30,31]

Distribution

Animal tests indicate inorganic tin is distributed into all tissues except the testis.[32] The highest tin concentrations appear in the liver, kidney, and bone with lesser amounts in other tissues. The clearance of tin from bone is slower than other compartments; therefore, bone is the main site of deposition of tin.[1,33] A majority (i.e., ~80%) of tin in the blood exists in the erythrocytes.[31]

Elimination

The results of animal and human studies on the elimination of tin from the body are somewhat inconsistent, primarily as a result of methodological differences. Excretion of tin absorbed into the body probably occurs primarily by the kidney with smaller amounts of tin excreted in the bile;[31,34] the tin concentration is substantially higher in urine than bile. Clearance of tin from the bone displays the longest half-life with a biological half-life of ~400 days.[30]

Maternal–Fetal Kinetics

Inorganic tin does not easily cross the placenta. The very low inorganic tin concentrations in the fetus during chronic feeding studies in rodents and the lack of developmental effects suggest the placenta restricts the passage of inorganic tin into the fetus.[31]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Although tin is an essential trace element in animals,[35] the specific biological actions of tin are unknown. In rodents, tin binds to 5-aminolevulinate hydrolyase (ALA dehydratase) and thereby inhibits ALA dehydratase activity.[36] The simultaneous injection of selenium prevents the binding of tin to ALA dehydratase.

CLINICAL RESPONSE

Acute Toxicity

Inorganic tin is relatively nontoxic; however, inorganic tin compounds may produce upper respiratory tract or gastrointestinal irritation. Although the corrosive properties of inorganic tin salts produce gastrointestinal disturbances in high doses, poor oral absorption limits systemic toxicity. Nausea, vomiting, diarrhea, and abdominal pain develop soon after the ingestion of food or drink contaminated with tin.[37]

Environmental Exposure

Environmental exposure to tin is not typically associated with toxicity in the general population as a result of relatively low elemental toxicity and limited exposure. Sensitization to inorganic tin is rare. In a series of 2,206 patients skin tested at a Danish dermatology clinic, five patients (four women, one man) tested positive to 1% $SnCl_2$ patch test.[38] This reaction was nonirritant.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Occupational Exposure

Exposure to tin oxide fumes may cause metal-fume fever manifested by vomiting, myalgias, bronchitis, and pulmonary infiltrates. Workers in glass bottle factories where the combination of stannic chloride and water produces HCl commonly complain of cough, dyspnea, chest pain, and wheezing;[39] however, pulmonary function test results usually remain normal. Inhalation of dust or fumes from stannic oxide for 15–20 years produces a benign pneumoconiosis known as stannosis;[40] case series indicate these workers develop dense radiopacities on chest X-rays without evidence of pulmonary dysfunction despite the gross radiological abnormalities.[41] Massive fibrosis following exposure to tin oxide dust typically does not occur in workers with stannosis.[42] A case report associated the development of interstitial pneumonia with chronic exposure to indium-tin oxide dusts, but tin was a relatively small (10%) component of this oxide.[43,44] Inorganic tin is a rare cause of allergic dermatitis in the occupational setting.[45,46] A case report described the development of chest tightness, dry cough, and wheezing in a chronic smoker 36 hours after her flooded office was sprayed with a fungicide containing tributyltin oxide.[47] During a challenge test with the carpet solution 7 months after exposure, she had a 19% fall in FEV_1 1 hour after exposure. The authors opined that tributyltin oxide was the likely etiology of the patient's respiratory symptoms.

Reproductive Abnormalities

Inorganic tin is not usually associated with abnormalities in fetal development. In a study of lactating mothers of premature and full-term infants, the tin concentrations in successive milk samples did not display any pattern indicative of biological regulation and potential human requirements.[48]

Carcinogenesis

Neither the IARC nor the US NTP lists tin or tin compounds as suspected carcinogens. There are few epidemiological data on the carcinogenicity of these compounds. Most chronic animal studies on inorganic tin compounds are negative (e.g., stannous chloride) including organotin compounds (e.g., tributyltin).[6,49]

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 0.008424 μmol/L
1 μmol = 118.7 μg/L

Analytical Methods

Techniques for analyzing tin concentrations in biological or environmental samples usually involve the determination of tin as a total metal rather than a specific tin species.[6] Older methods involved flame/atomic absorption spectrometry; however, low sensitivity and loss of tin oxide during combustion limit the usefulness of these techniques. Newer techniques improve the sensitivity and reduce the loss of tin oxide with combustion. The most common and simplest method for the detection of tin is flame atomic absorption spectrometry, but graphite furnace/atomic absorption spectrometry, inductively coupled plasma/mass spectrometry, and inductively coupled argon plasma/atomic emission spectrometry are more sensitive (<0.1–1 μg Sn/L) for quantitation of tin in biological and environmental samples.[50,51]

Biomarkers

Based on recent mass spectrometry studies and neutron activation analysis, the average whole blood tin concentration in the general population is low (few μg/L), depending on tin exposure in the diet. The mean whole blood total tin concentration in a master mixture of equal aliquots from 2,500 healthy UK residents during the early 1970s was ~5 ± 2 μg/L (ppm, wet weight) as measured by spark source/mass spectrometry with thermal ionization.[33] In whole blood samples from 14 Italian adults, the tin concentration was below the limit of detection (2 μg/L) in all samples as measured by radiochemical activation analysis during the late 1970s,[52] whereas the median tin concentration in a study of 99 healthy French children was 0.96 μg/L (95% CI: 0.41–4.03 μg/L).[53] The corresponding median plasma tin concentration in the latter study was 1.8 μg/L (95% CI: <1.0–4.7 μg/L). About 80% of whole blood tin resides in the erythrocytes; therefore, plasma tin concentrations are extremely low. Twenty-four-hour urine tin concentrations in the general population range from ~1–20 μg/L.[54] Collection of the urine for tin confirms excessive exposure to tin.

Abnormalities

In symptomatic workers from glass bottle factories exposed to stannic chloride aerosolized HCl, pulmonary function tests usually remain normal.[39] The high atomic weight of tin produces prominent radiopaque lesions on chest X-rays, but little tissue reaction (fibrosis) occurs as a result of the inhalation of tin.[55]

HEALTH SURVEILLANCE

Table 31.2 lists regulatory levels and guidelines for elemental tin and inorganic tin compounds. The ATSDR determined a intermediate-duration minimal risk level of 0.3 mg/kg/day based on a NOAEL of 32 mg Sn/kg/day as stannous chloride for hematological effects (reduced hemoglobin content and cell volume) in a 13-week study of rats.[56] The ACGIH derived an 8-hour TLV–TWA of 2 mg/m^3 for elemental tin and tin oxides to minimize the risk of mild pneumoconiosis (i.e., stannosis).

TREATMENT

The treatment of elemental tin and inorganic tin toxicity is supportive. Decontamination measures are usually unnecessary. Exposure usually results in gastrointestinal tract irritation or mild upper respiratory tract irritation that responds to removal from exposure and symptomatic care. Systemic toxicity is rare; the presence of serious abnormalities in vital signs or persistent clinical symptoms suggests exposure to another etiology.

TABLE 31.2. Regulatory levels and guidelines for elemental and inorganic tin exposure.

Exposure Limit	Value
OSHA	
PEL-TWA (8-hour)	
Inorganic compounds[b]	2.0 mg Sn/m^3
Tin oxide[d]	
(total dust)	15 mg Sn/m^3
(respirable fraction)	5.0 mg Sn/m^3

ORGANIC TIN

HISTORY

Although the first organotin compound was synthesized by Lowig in 1852, the first commercial application did not occur until the issuing of patents for the use of organotin compounds as stabilizers of transformer oils (1932) and vinyl plastic (1940). The commercial use of organotin compounds has expanded rapidly over the last 40 years as biocidal agents, catalysts, and heat stabilizers for polyvinyl chloride polymers.[57]

In France, a diethyltin preparation (Stalinon) was sold as a treatment for acne, anthrax, furunculosis, and osteomyelitis; this product was withdrawn from the French market in 1960 following the outbreak of a fatal neurological disease associated with the Stalinon use in 1954. Of the ~1,000 people ingesting this drug during the outbreak, 217 developed the illness, and 102 died. Triethyltin iodide, which is 10 times more toxic than diethyltin, contaminated up to 10% of the tin present in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Stalinon.[3] The most common symptom was headache that appeared after a 4-day latent period. Vertigo, urinary retention, vomiting, photophobia, and abdominal pain were also common symptoms. Paresthesias, headaches, and visual abnormalities persisted for years in some patients; complete recovery occurred in only ~10% of the severe cases.[58]

Organic tin compounds (e.g., tributyltin, triphenyltin) are endocrine disruptors in marine animals, particularly mollusks.[59] In the 1970s, the use of organotin (i.e., tributyltin) in antifouling paints was associated with the decline of coastal marine mollusks as a result of the phenomenon of the superimposition of male sexual characteristics (e.g., penis) on female gastropods (i.e., imposex). In 2008, the International Maritime Organization banned the application of TBT-based points.

PHYSIOCHEMICAL PROPERTIES

Organic tin compounds form covalent bonds between at least one of three carbon atoms and a tin atom; the number of covalent carbon-tin bonds (mono, di, tri, tetra) characterizes organotin compounds. Stannic compounds are covalent; the ionic form of Sn^{4+} does not exist naturally. Almost all commercially important organotin compounds possess a tetravalent structure. For industrial compounds, the most important organic constituents are methyl, butyl, octyl, and phenyl groups, whereas the most important anions are carboxylate, chloride, fluoride, hydroxide, oxide, and thiolate.[60] Table 31.3 lists some physiochemical properties of methyl-, butyl-, dimethyl-, and dibutyltin compounds.

Tributyltin compounds are organic derivatives of Sn^{4+} that possess different chemical properties than inorganic tin compounds depending on the chemical group covalently bonded to Sn. Tributyltin compounds are lipophilic and possess relatively low water solubility. Tributyltin oxide is a mild oxidizing agent with an octanol/water partition coefficient (log K_{ow}) of 3.19–3.84.[61] The vapor pressure of tributyltin compounds is very low; little loss of tributyltin oxide occurs from solution over 60 days, even though 20% of the water evaporates.[62] Triphenyltin compounds (e.g., hydroxide, acetate, chloride) are triphenyl derivatives of tetravalent tin. At ambient temperature in the neutral pH range (3–8), triphenyltin acetate and triphenyltin chloride hydrolyze to triphenyl hydroxide in a few minutes.[63] Triphenyl compounds are generally lipophilic, and their water solubility is low (few mg/L).[63] Table 31.4 lists the identifying information and physical properties of trimethyltin and similar covalent compounds. Tetrabutyltin (tetrabutylstannane, CAS RN: 1461-25-2) is an odorless to slightly yellow oily liquid that is insoluble in water.

EXPOSURE

Production Processes

The manufacturing of organotin compounds involves chemical processes. Comproportionation reactions (i.e., two differently charged ions of the same element reacting to form two equally charged ions) between tin tetrachloride and organotin compounds produce mono-, di-, and tri-organotin derivatives. Processes using Grignard reagent or organic-aluminum compounds form tetraalkyl and tetraaryltin compounds.

Uses

The major uses of organotin compounds include PVC heat stabilizers, biocides, catalysts, agrochemicals,

and glass coatings.[6] Mono- and di-substituted organotin compounds are stabilizers in plastics, whereas tri-substituted organotin compounds are primarily biocides. The concentration of organotin compounds in PVC is ~1–1.5%.[64] Octyl- and methyltin compounds are constituents of PVC in food packaging. Alkyltin chloride inhibits the dissociation of hydrochloric acid from polyvinyl chloride. When bound to the plastic, the organotin compounds do not produce toxicity. These compounds are also added to polyurethane foams and silicone to reduce odor and strengthen their structure. Tributyltin (TBT) and triphenyltin (TPT) compounds have been used as marine anti-fouling compounds, molluscicidal agents, wood preservatives, disinfectants, slimicides, and biocidal agents since the 1960s, but these uses have been gradually banned. TPT is an antifungal agent for rice, potatoes, sugar beets, hops, and celery.[65] Initially, many countries banned the use of TBT and TPT antifouling paints for boats of <25 m in size to reduce the effects of TBT on the aquatic ecosystem, particularly shellfish. The content of TBT is restricted to reduce the leaching of TBT from paint to <4–5 μg TBT/cm^2/day.[66] Tetra-*n*-butyltin has been used as a gasoline additive.

Sources

Organotin compounds are not typically part of the natural environment. Anthropogenic sources release organotin compounds into the environment; however, biomethylation of inorganic tin to methyltin compounds can occur naturally or anthropogenically as stabilizers in PVC products.[67] Butyltin compounds exist only as a result of anthropogenic sources; however, marine sources in the diet provide the main exposure to butyltin compounds based on the presence of these compounds in postmortem specimens of human livers.[68] The presence of tributyltin compounds in antifouling coatings is a significant source of these compounds in marine and freshwater environments. The only source of octyltin compounds is the use of these compounds as stabilizers in PVC products. These latter compounds do not usually appear in water or sediments. The use of antifouling paints is the major source of tributyltin in the coastal environment, whereas triphenyltin compounds enter the environment primarily from use as pesticides.

Air

Although little data on the volatilization of organotin compounds from water exist, *in vitro* testing of tributyltin in water indicates that this organotin does not partition into the air.[62]

Soil

The adsorption of trisubstituted organotin compounds to suspended particulate matter, low water solubility, and poor mobility result in the accumulation of these compounds and their degradation products in sediment. High concentrations of TBT (e.g., up to 14 μg/g sediment) may occur in the bottom sediment of ship channels, marinas, harbors, or ports.[69] In a study of sediments from Goteborg Harbor in Sweden, the TBT and TPT concentrations (dry weight) ranged from 17–366 ng/g and 1.5–71 ng/g, respectively.[70] Sediments

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

under coastal waters may contain complex degraded organotin compounds (e.g., di-*n*-butyloctyltin chloride, di-*n*-butyl(2-methylhexyl)tin chloride).[71]

Water

Commercial applications (e.g., agriculture, antifouling coatings on ships, stabilizers in polyvinyl chloride plastic) account for the release of organic tin compounds into the water. In a Canadian study on organotin compounds in drinking water from houses with recently installed (i.e., <6 months) PVC pipes, the maximum organotin concentrations in water from these houses were 291 ng Sn/L for methyltin, 49.1 ng Sn/L for dimethyltin, 28.5 ng Sn/L for butyltin, and 52.3 ng Sn/L for dibutyltin.[72] However, the water in most of these houses contained no detectable organotin compounds.

In general, the concentration of TBT ranges from 1–10 ng/L in coastal waters and estuaries with higher concentrations (i.e., up to 1.3 μg/L) occurring in marinas and major ports.[61] Maximum concentration of TBT in marine water rarely exceeds 100 ng/L except in locally contaminated areas (e.g., newly industrialized countries).[73] Concentrations of tributyltin (TBT) up to 1.58 μg/L in seawater and up to 7.1 μg/L may occur in areas near pleasure-boating activities.[66] The actual TBT concentration is usually less and depends on the use of antifouling paints, the degree of tidal flushing, and the turbidity of the water. The TBT concentrations in freshwater marinas demonstrate seasonal variation with the highest concentrations occurring in late spring and the lowest in winter.[74] Sampling techniques may produce abnormally high organic tin concentrations, particularly if the samples contain paint particles or if the sample consists primarily of the surface microlayer.[61]

Diet

Exposure to organotin compounds occurs primarily following the ingestion of organotin-containing seafood and, to a lesser extent, contact with consumer products that contain organotin compounds.[6] The estimated daily intakes of tributyltin (TBT) and triphenyltin (TPT) compounds from the Japanese diet during the early 1990s as measured by the duplicate portion method were 2.2–4.7 μg and 0.7 μg, respectively, whereas the market basket method results were 6.7–6.9 μg and 1.3–5.4 μg, respectively.[75] In a study of organotin intake from fish consumption in Finland, the estimated average daily intake of organotin compounds (dibutyltin, tributyltin, triphenyltin, dioctyltin) was 3.2 ng/kg bodyweight.[76] Domestic wild fish (e.g., herring, pike, perch) accounted for 61% of the total organotin intake compared with 35% for imported fish (e.g., salmon, rainbow trout, tuna, herring, shrimp) and 4% for farmed fish (e.g., rainbow trout).

Butyltin and phenyltin accumulate in the marine food chain, resulting in elevated tin concentrations in marine organisms (e.g., crabs, fish, oysters). The concentration of butyltin compounds is usually low (ng/g range).[77] The highest concentrations (i.e., 100–1,500 ng/g) of butyltin compounds in marine food occur in cultured fish and molluscs, particularly in Asia.[78] Butyltin compounds can accumulate in the liver and kidney of higher trophic animals including marine predators (dolphins, sharks, tuna). The concentration of total butyltin compounds ranged up to 980 ng/g wet weight in samples collected from deepwater fish near Japan,[79] up to 2,610 ng/g wet weight in river otters near Puget Sound in Washington,[80] and up to 2,200 ng/g wet weight liver in dolphin caught off the coast of Italy.[81] Accumulation of these compounds is about an order of magnitude higher in liver and kidney than subcutaneous fat.

Triphenyltin and tributyltin compounds are found mostly in seafood, particularly in marine fish. The presence of TPT in coastal and pelagic (open-ocean) fish from Tokyo fish markets suggests limited biomagnification of these compounds may occur in the food chain. Biological monitoring of Japanese coastal fish indicates decreasing concentrations of organotin compounds as a result of the restrictions on the use of these compounds in marine paint. In 1989, ~60% of the coastal fish contained triphenyltin at concentrations ranging up to 2.6 μg/g wet weight in muscle, whereas 30% of the samples were positive in 1995 with a range up to 0.25 μg/g wet weight in muscle.[63] The mean TPT concentration in pelagic fish was 0.048 μg/g, and freshwater fish were relatively uncontaminated.

ENVIRONMENTAL FATE

Most organotin compounds are sparingly soluble in water, resulting in the partition of these compounds into soils and sediments. The low vapor pressures, low water solubilities, and high affinities of soil and organic sediments significantly limit the mobility of commercial organotin compounds in environmental media.[82] Progressive elimination of organic groups from the tin cations results in the degradation of organotin compounds in the environment depending on temperature, light, and pH. Anaerobic environments may retain hydrophobic organotin compounds for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

years in sediment.[67] Photodecomposition by ultraviolet light is the most important degradation process in air, whereas biological processes are more important in soil and water.[83] Degradation of triphenyltin and tributyltin occurs by the cleavage of the tin–carbon bond through biological, chemical, and UV radiation, resulting in sequential dephenylation and debutylation, respectively. Biodegradation of the organotin compounds depends on environmental conditions (e.g., temperature, pH, tin, oxygen concentrations) and the type of microflora. Under favorable conditions, TBT degrades to DBT, then to MBT, and ultimately to inorganic tin.[84] Elevated temperatures, aerobic conditions, and intense sunlight enhance this degradation;[63] however, hydrolysis and photolysis of organotin compounds are limited under normal environmental conditions.[61]

Air

There are few data on the concentrations of organotin compounds in the air. Low vapor pressures and rapid photodegradation significantly limit the release of organotin compounds into the air.[67]

Soil

In general, the measured half-lives of dialkyltins in soils are ~120–150 days in laboratory tests, whereas methyltins and butyltins are more persistent in forest soils with half-lives ranging from 6 months–15 years.[64] Persistence of triphenyltin acetate and triphenyltin hydroxide depends on soil type and pH. The uptake of triphenyltin hydroxide by plants is extremely low because of the strong adherence of this compound to soil.[63] The half-life of this compound in sandy loam soils was 1–3 months with saturation of the soil increasing the half-life to 126 days.[85] Microorganisms degrade triphenyltin compounds into inorganic tin and carbon dioxide.

Degradation of organotin compounds in the soil is much slower (i.e., several years) in sediment than in water. In marine sediment, tributyltin occurs primarily in the upper layers, where the estimated half-life is ~2 years.[86] Based on a first-order multi-step kinetic model of the sequential degradation of tributyltin, the estimated half-lives of dibutyltin and butyltin are 1.9 and 1.1 years, respectively. These degradation products are typically present in the lower layers of marine sediment. The slow release of TBT into the aquatic system results in exposure of gastropods and filter-feeding organisms to substantial amounts of TBT.

Water

The low water solubility and the lipophilic nature of TBT promote TBT adsorption onto particles (sediment) depending on environmental conditions (quantity and physical characteristics of particles, temperature, presence of dissolved organic matter, salinity). The affinity for adsorption of organobutyltin compounds increases with increasing tin substitutions (i.e., TBT > DBT > MBT).[87] Bioavailability of organotin compounds depends primarily on pH and the presence of humic acids/dissolved organic carbon; the presence of dissolved organic carbon decreases organotin bioavailability, whereas neutral or slightly alkaline pH enhances bioavailability.

The persistence of organotin compounds depends on the interaction of several processes including fast and reversible adsorption/desorption, slow anaerobic biotic and abiotic degradation, and moderate to fast aerobic biotic degradation. The fate of TBT usually results from degradation rather than desorption.[88] In general, the half-life of tributyltin in water is several days to weeks, but tributyltin compounds can persist in sediments for several years depending on soil conditions.[61] Tributyltin has a relatively short half-life in water (~6 days under optimum conditions), but the half-life increases to almost 2 years in anaerobic environments like sediment.[89] *In vitro* studies indicate TBT degrades faster ($t_{1/2}$ = 28 days) in organic-rich sediment than sandy organic-poor sediment ($t_{1/2}$ = 78 days).[87] TBT undergoes photolysis with a fairly long half-life of ~3 months in sedentary waters, but the role of photodegradation in the removal of tributyltin is limited by the poor penetration of UV light into the water.[62] Consequently, the estimated half-life of TBT in surface (river) water was substantially less (3–13 days).[90] Direct photolysis results in the sequential loss of butyl groups; inorganic tin is the residual product. There is no evidence of biomagnification (i.e., uptake from the food chain) of tributyltin in marine ecosystems, but bioaccumulation (i.e., uptake from water, sediment phase, and food chain) may occur from the ingestion of organisms with high tissue concentrations of TBT.[91]

The hydrolysis of TPT compounds in water produces triphenyltin hydroxide and various hydrated oxides. The chloride in seawater reacts with hydrated cations to form the covalent organotin chloride that is less water-soluble than TPT.[63]

Food Chain

As a result of the lipophilicity of TBT, the TBT concentrations in organisms living in water containing TBT

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

are greater than TBT concentrations in the surrounding water. Laboratory studies indicate the bioconcentration of TBT in mollusks and fish from surrounding water is up to 7,000 times.[92] Bioaccumulation of TBT in bivalves (i.e., up to 5 ppm) is especially high because of their limited metabolism of TBT;[61] the bioaccumulation is greater in cetaceans than pinnipeds.[93] Fish accumulate substantially less TBT than marine bivalves because of their greater ability to degrade TBT. Recent studies indicate TBT accumulation is greater in the liver and kidney than subcutaneous fat, perhaps as a result of the binding of TBT to proteins in the liver and kidney.[94] Evidence for the transfer (i.e., biomagnification) of TBT through the food chain is limited with biomagnification substantially less important than the bioconcentration of organotin from the water phase.[66,88] The biomagnification factor in harbor porpoises in Turkish coastal waters of the Black Sea was 0.8; this value is comparable to pinnipeds and lower than cetaceans.[95] The residues of organotin compounds in these studies are substantially higher in fish from coastal waters and developed countries than open-sea fish, particularly near developing countries.

Studies of TPT compounds (triphenyltin chloride) in experimental conditions revealed the bioconcentration factor (BCF) of daphnids did not exceed 300; the BCF in fish ranged from 257–4,100.[96] In these studies, the accumulation of organotin compounds did not correlate with fat content; in marine fish, the BCF was higher for TBT than TPT.

The biological half-lives of TPT in short-necked clams were ~30 days compared with 139 days for mussels from a busy Japanese port.[97] The biological half-lives of TPT and TBT compounds in a benthic predator (*Buccinum undatum*) that feeds predominately on live benthic bivalve molluscs and dead animals near the Netherlands were ~1 year with Sn concentrations ranging up to 625 ng/g dry weight and 40 ng/g dry weight, respectively.[98] The order of tissue accumulation for butyltin compounds was dibutyltin > monobutyltin > tributyltin. Studies of organotin compounds in freshwater demonstrated benthic organisms accumulate TPT from the sediment; at higher trophic levels, the net bioaccumulation of TPT compounds exceeds that of TBT compounds.[99] The accumulation of TPT compounds at higher trophic levels occurred via mechanisms different from traditional lipophilic compounds because TPT concentrations were greater in the liver and kidney than subcutaneous fat. Although biomagnification of TBT (tributyltin) compounds probably does not occur, examination of organotin compounds in mussels (*Mytilus edulis*), common whelks (*B. undatum*), and sediment from marine waters near the Netherlands suggests some biomagnification of TPT (triphenyltin) compounds may occur.[100] The TPT concentrations in whole-body homogenates of common whelks from the Eastern Scheldt of the Netherlands were 4–100 times higher than TBT concentrations.

DOSE EFFECT

In general, the toxicity is greater for trisubstituted organotin compounds than for monosubstituted and disubstituted organotin compounds. The toxicity of trialkyltin compounds decreases as the number of carbon atoms in the alkyl chain increases. TBT is toxic to microorganisms; susceptibility varies with different species. Algicidal tributyltin oxide (TBTO) concentrations also vary with species ranging from <1.5 to >1000 μg/L.[66] The estimated toxic dose in adults ingesting triethyltin iodide during the Stalinon epidemic in France was 70 mg triethyltin iodide over 8 days.[101] Subacute animal studies suggest Sn doses of 12–25 mg/kg for 30–90 days produce inflammation and hyperplasia of the bile duct with necrosis in the liver.[102]

TOXICOKINETICS

Absorption

Absorption is greater for organotin than inorganic tin compounds; organic tin compounds (e.g., dibutyltin, triphenyltin) are detectable in blood samples from the general population depending on exposure and individual kinetics of the specific compound.[103] Animal studies indicate the gastrointestinal tract absorbs triethyltin, trimethyltin, tributyltin, and dibutyltin well, but the absorption of triphenyltin depends on the species. Good absorption of triphenyltin occurs in rats and guinea pigs, but sheep and cows absorb this compound poorly.[1] Case reports suggest acute organotin intoxication can occur following the intentional ingestion of 60% triphenyltin acetate-containing molluscicide[104] and inhalation of vapor/dusts from triphenyltin acetate-containing fungicides.[105] Absorption of tributyltin compounds varies between 20–50% following ingestion compared with ~10% of a TBT dose applied to the skin.[66] Based on the limited data available on the dermal absorption of tin compounds, absorption of these compounds through the skin is not a major route of exposure.

Distribution

Limited diffusion of methyltin, butyltin, and octyltin occurs across the blood–brain barrier with relatively

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

low concentrations in the brain.[64] In animals, the distribution of organic tin is similar to the distribution of inorganic tin.

Elimination

The liver transforms most organic tin compounds by dealkylation with inorganic tin being the residual compound. Analysis of urine samples from patients poisoned by dimethyltin-contaminated cooking oil suggests dimethyltin compounds may be methylated to trimethyltin compounds after absorption.[106] Renal excretion accounts for most tin eliminated by the body with smaller amounts of tin appearing in the bile;[31] however, the contribution of biliary excretion is relatively greater for organotin than inorganic tin compounds. The bile is the main excretory route for tributyltin and triphenyltin. The estimated biological half-life of TBT in mammals is ~23–30 days.[66,107]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Central Nervous System

Mechanism of Toxicity

The *lower* homologs of tetraalkyltin and trialkyltin compounds possess neurotoxic properties. The effects of tetraalkyltin compounds are similar to the effects of trialkyltin compounds because of the conversion of tetraalkyl tin compounds to trialkyltin compounds in the liver.[108] A molecular model for this neurotoxicity is not available. Like tri-organolead compounds, the main biochemical action of tri-organotin compounds is probably the inhibition of mitochondrial enzyme systems.[109]

Pathological Changes

Trimethyltin compounds produce necrosis of the hippocampus in both animals[110,111] and humans.[112] In rats treated with a single oral dose of 7 mg trimethyltin/kg, convulsions, irritability, hyperactivity, and impairment of spatial discrimination develop.[113] Histological studies of these rats reveal pathological changes in the limbic structures, particularly the pyramidal cells in CA1 and CA4. Localized neuronal damage occurs to a lesser extent in the pyriform cortex, the amygdaloid nucleus, brainstem, neocortex, spinal cord, retina, sensory neurons, and cochlea.[114,115] Exposure of rats to trimethyltin causes high-frequency hearing loss associated with cochlear damage.[116] Triethyltin compounds demonstrate less neurotoxicity than trimethyltin compounds. In contrast to the neuronal necrosis produced by trimethyltin in rats, exposure of rats to triethyltin causes cerebral edema and neuronal changes that often are reversible.[117]

Postmortem

The primary pathological features involve necrosis in the limbic system structures (e.g., amygdala) and cerebellar Purkinje's cells. Electron microscopy reveals many cytoplasmic lamellated inclusions (zebra bodies) along with vacuoles and granulo-membranous particles. The presence of zebra bodies reflects increased activity of lysosomes. Morphological changes also appear in the temporal cortex, basal ganglia, and pontine nuclei. The major nonneurological findings on the autopsies of patients dying after exposure to trimethyltin include tracheobronchitis, pneumonia, severe acute pulmonary edema, fatty degeneration of the liver, and shock kidney.[118]

The main pathological findings in a 48-year-old woman dying 6 days after the ingestion of TMT involved the nervous system including generalized chromatolysis of the neurons in the brain, spinal cord, and spinal ganglia.[119] Neuronal necrosis in the fascia dentata of the hippocampus and spinal ganglia probably resulted from TMT toxicity, whereas pre-terminal anoxic injury could not be excluded as a cause of recent necrosis in pyramidal cell layers (hippocampus, cerebral cortex, basal ganglia) and the Purkinje cell layer of the cerebellum. Electron microscopy demonstrated marked accumulation of lysosomal dense bodies and disorganization of the granular endoplasmic reticulum in the neurons, but no cytoplasmic zebra bodies were detected. In contrast to the localized neuronal alterations in the limbic system produced by TMT exposure, triethyltin exposure causes a diffuse edema of the myelin sheaths (i.e., intramyelinic edema) in the brain.[120]

Immune System

Various *in vitro* and rodent studies indicate dialkyl tin compounds[121] and tributyltin oxide[122] suppress cell-mediated immunity, but there are few data in humans to support the production of immunological abnormalities in humans following exposure to these organotin compounds. In animal studies, tributyltin and dibutyltin compounds produce less neurotoxic effects than trimethyltin or triethyltin compounds.[123] Studies in mammals indicate tributyltin oxide exposure produces adverse immune effects (leukopenia,[124] thymus-dependent immunity[125]). Dibutyl dichloride

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. and tributyltin compounds are primary skin irritants that cause slightly delayed (1–2 hours) pruritic, erythematous skin lesions.[126]

CLINICAL RESPONSE

Acute Toxicity

Inhalation of tributyltin oxide may cause upper respiratory tract irritation. A case report attributed the development of asthma in a 52-year-old atopic patient with a 32-pack-year smoking history to exposure to a carpet deodorizer containing tributyltin oxide.[47] However, workers involved with the manufacture of dibutyl and tributyltin compounds have not demonstrated an excess incidence of respiratory abnormalities despite the presence of skin irritation.[126] A case report associated triphenyltin exposure with the development of nausea, vomiting, abdominal pain, general malaise, weakness, dizziness, and transient elevation of hepatic transaminases that resolved without sequelae.[127]

Tributyltin compounds are irritants of the skin and mucous membrane that may cause cutaneous lesions and irritation of the conjunctiva and nasal mucosa. Cutaneous burns develop within several hours *after* dermal contact with dibutyltin or tributyltin compounds (acetate, chlorides, laurate, oxides). The most prominent sign is inflammation of the hair follicles that progresses to minute pustules within 2 days. These lesions are more pruritic than painful. Both irritant effects and a contact dermatitis developed in painters applying formulations containing tributyltin oxide (TBTO) concentrations as small as 0.6% TBTO.[128] Recovery from these lesions is usually complete within 1–2 weeks. Triphenyltin hydroxide compounds present in pesticide formulations are moderately strong irritants, but these compounds do not produce strong hypersensitivity reactions based on patch testing of workers exposed to these compounds.[129]

Serious neurological abnormalities may occur after exposure to high doses of organotin compounds, particularly trimethyltin (TMT). Other organotin compounds (e.g., triethyltin (TET), triphenyltin (TPT)) are much less potent central nervous system toxins. Acute exposure to high TMT doses causes clinical signs of dysfunction of the limbic system and cerebellum along with hearing loss and mild sensory changes. Examples of limbic dysfunction include confabulation, retrograde and anterograde amnesia, aggressiveness, hyperphagia, and abnormal sexual behavior.[118] Additionally, short-term memory loss may develop 72 hours after TMT exposure that improves over the next 3 months.[130]

A 48-year-old woman developed tinnitus, lightheadedness, aggression, and episodes of unresponsiveness after the ingestion of an unknown amount of TMT; her clinical course progressed to multiorgan failure and death 6 days after ingestion.[119]

Environmental Exposure

Five family members developed mucous membrane irritation following the painting of the second story of their house with paint with a mildew control agent containing 25% bis(tributyltin) oxide.[131] Symptoms included headache, nausea, vomiting, sore throat, burning nose, watery eyes, and wheezing. On physical examination the day after painting, two children had wheezing; oxygen saturations by pulse oximetry and chest X-rays were all normal. Follow-up 5 days after the painting indicated all symptoms resolved without sequelae.

Occupational Exposure

Case reports associate neurological (headache, memory loss, poor balance, tinnitus, cerebellar dysfunction, leukoencephalopathy) and psychiatric (hallucinations, emotional volatility, temper tantrums, aggressive behavior, apathy) symptoms in workers following excessive exposure to dimethyltin (DMT) and trimethyltin (TMT). Clinical features of acute exposure to high TET doses include symptoms of increased intracranial pressure, generalized tonic-clonic seizures, and paralysis. In contrast to TET-induced effects from the Stalinon epidemic, trimethyltin exposure produces predominantly clinical signs of limbic system dysfunction (e.g., disorientation, confabulation, amnesia, aggressiveness, disturbances of sexual behavior), cerebellar signs (e.g., nystagmus, ataxia), hearing loss, and mild sensory disturbances. Mild exposure to TPT-containing agricultural fungicides produces nausea, vomiting, headache, vertigo, impaired vision, photophobia, weakness, paresthesias, convulsions, and transient loss of consciousness.[105]

Dimethyltin

Clinical features of DMT toxicity include aggressiveness, amnesia, ataxia, confabulation, disorientation, hearing loss, nystagmus, paresthesias, partial-complex/tonic-clonic seizures, and sexual dysfunction.[118] A 43-year-old tank cleaner developed disorientation, visual hallucinations, and agitation 3 days after cleaning a storage tank containing dimethyltin.[132] Within 2 days,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

he developed coma, respiratory failure, acute hepatorenal failure, and rhabdomyolysis. His urine contained dimethyl and trimethyltin. Ataxia, dysarthria, and retrograde amnesia persisted 19 months after dimethyltin exposure. Diffuse myalgias and partial-complex or grand mal seizures may complicate the clinical picture. Two chemists developed seizures while synthesizing dimethyltin chloride over 3 months; neither patient had a prior history of seizures; the seizures resolved after cessation of exposure.[133] Other symptoms during their intermittent exposure to dimethyltin chloride included memory impairment, poor vigilance, insomnia, anorexia, disorientation, and headache. The case report contained no airborne tin measurements or analyses of tin in biological specimens.

Trimethyltin

One day after cleaning a tank containing TMT for 4 days, a 43-year-old man complained of disorientation, hallucination, irritability, lightheadedness, and memory impairment.[134] He became comatose, requiring intubation within 3 days. Although he improved with intensive supportive care, memory impairment, moderate motor ataxia, disorientation, and difficulty speaking persisted 6 months later. Six chemical workers were exposed to variable amounts of vapor from a solution of 75% dimethyltin and 25% trimethyltin chloride during a maximum of nine 10-minute episodes. The normal vapor pressure of trimethyltin is substantially higher than that of dimethyltin.[112] After a latent period of 1–3 days, headache, tinnitus, deafness, memory loss, disorientation, psychosis, coma, and respiratory depression developed in the workers; one worker died. Neurological disabilities in the most severely affected workers persisted for at least 6 years including extrapyramidal hyperkinesias, memory impairment, and personality changes (e.g., aggressiveness). These workers did not have pulmonary sequelae. A case series of 22 chemical workers exposed to TMT chloride, DMT dichloride, and methyl chloride reported residual neurological and psychiatric symptoms (depression, irritability, marital difficulties, forgetfulness, loss of motivation, volatility) in four workers followed for ~3 years; three of these workers did not return to the workplace during the follow-up period.[135] The study did not correlate symptoms to urine tin concentration; no ambient air tin concentrations were measured.

Reproductive Abnormalities

Limited data are available on the developmental and reproductive effects of tin compounds. In experimental studies of rodents at doses of tributyltin oxide and tributyltin acetate that produce toxic effects in the mother, an increased incidence of fetal deaths and resorptions[136] occur along with an increase in the number of cleft palates and cervical ribs.[137] The relevance of these studies at tin concentrations currently present in the work environments or the general population is unclear because of the presence of maternal toxicity at these very large doses of tributyltin compounds. In a study of Wistar rats exposed to di-*n*-butyltin dichloride, the NOAEL for malformations was 1.7–5 mg/kg body weight, which was associated with substantial maternal toxicity.[138] This NOAEL was about 1/3 the value of the LD_{50} for this tin compound.

Carcinogenesis

Neither the IARC nor the US NTP lists organotin compounds as suspected carcinogens. Chronic feeding studies of rats using the organotin compounds, stannous octoate and sodium chlorostannate, did not demonstrate evidence of carcinogenicity.[49] An increased incidence of benign tumors at 50 mg TBTO/kg diet raises the possibility of carcinogenic effects, but the relevance of this data to humans is questionable.[66] A 2-year study of rats daily fed up to 2.5 mg tributyltin oxide/kg demonstrated an increased incidence of some tumors (pheochromocytomas, parathyroid, pancreatic, prolactinomas), but the high spontaneous incidence of these tumors and the lack of dose-response relationships limit conclusions regarding the significance of these tumors.[139] Although a 2-year rat feeding study with dietary concentrations of 0, 5, 20, and 80 ppm triphenyltin hydroxide detected an increased incidence of pituitary adenomas in females and an increase in testicular Leydig cell tumors at higher doses, the low survival rate limits conclusions regarding carcinogenicity.[63] The presence of Leydig cell hyperplasia and adenomas in rodent studies has limited relevance to human risks because of the hormonal mode of action in rodents.[140] TPT compounds probably are not genotoxic.[65]

DIAGNOSTIC TESTING

Analytical Methods

Atomic absorption spectrometry can separate organic tin compounds from inorganic tin following either liquid extraction or adsorption onto a solid matrix followed by re-extraction and/or concentration.[63] Other detection methods include gas chromatography

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with flame photometric or mass spectrometric detection[141,142] and normal-phase liquid chromatography with ultraviolet or fluorescence detection.[143–145] Methods to quantitate organic tin compounds include gas chromatography/mass spectrometry,[146] and ion-pair/reversed-phase chromatography/hydride generation-quartz furnace/atomic absorption spectrometry.[147] The latter technique allows the speciation of TBT, TPT, and DBT. Graphite furnace/atomic absorption spectrometry with liquid extraction or adsorption onto a solid matrix and then re-extraction and/or concentration can separate inorganic tin and quantitate organic tin compounds.[63]

Organotin compounds can also be separated from biological samples by capillary supercritical fluid chromatography and measured by inductively coupled plasma/mass spectrometry with detection limits near 12 pg.[148] Gas chromatographic methods require conversion of ionic alkyltin compounds either by *in situ* hybridization (sodium borohydride) or alkylation (sodium tetraethylborate).[149] Analytical methods for the speciation of organotin compounds include high-performance liquid chromatography coupled with atomic absorption spectrometry.[150] Limits of detection range from ~0.15–0.60 μg Sn/L, whereas the limits of quantitation range from ~0.5–2.0 μg Sn/L. Butyltin compounds are stable in ambient and refrigerated conditions for at least 1 month.[141]

Biomarkers

Blood

In a study of blood samples from 32 volunteers in central Michigan, the following percentage of butyl tin compounds were detectable: butyltin, 53%; dibutyltin, 81%, and tributyltin, 70%.[151] The concentration of these compounds ranged up to 0.027 μg organotin ion/mL (monobutyltin), 0.016 μg organotin ion/mL (dibutyltin), and 0.085 μg organotin ion/mL (tributyltin). Two days after exposure to triphenyltin acetate, a 36-year-old man was admitted to the hospital with dizziness, malaise, nausea, abdominal pain, and mild liver dysfunction; his admission plasma tin concentration was ~78 μg/L.[127]

Urine

Collection of the urine for tin confirms recent excessive tin exposure. In a study of 500 urine samples from participants in the National Health and Nutrition Examination Survey (NHANES) III, conducted from 1988–1994, 89% of the urine samples had detectable concentrations of tin (LOD, 0.1 μg/L). The 95% CI was 20.1 μg/L.[152] In a worker developing gastrointestinal distress, abdominal pain, urticaria, and mild liver inflammation after exposure to triphenyltin acetate, the peak urine tin concentration of 96 μg/L occurred 6 days after exposure.[127] Maximal excretion of tin occurred 4–10 days after a large exposure to trimethyltin that produced neurological symptoms in workers exposed to organic tin.[118] In these workers, peak urine tin concentrations ranged from 445–1,580 μg/L compared with a mean urine level of 36 μg/L in asymptomatic workers exposed to organotin compounds at the same plant.

Abnormalities

Abnormal laboratory values following excessive exposure to organotin compounds included elevated hepatic aminotransferase levels, severe hypokalemia, hyperglycemia, increased serum creatine kinase concentrations (rhabdomyolysis), elevated serum creatinine (renal dysfunction), sensorimotor polyneuropathy, and leukocytosis.[134] The electroencephalogram may demonstrate moderate slowing of background activity (4–6 Hz) with periodic paroxysmal generalized spikes following TPT exposure or sharp waves or prolonged bilateral theta activity localized to the temporal region following TMT exposure. The initial MRI images from a 43-year-old man with organotin encephalopathy were normal 1 day after exposure; however, by 12 days post-exposure, the MRI demonstrated high-intensity signals in white matter of the cerebral hemisphere, posterior rim of the internal capsule, corpus callosum, cerebral peduncle, and corticospinal tract.[132] At that time, he was comatose.

HEALTH SURVEILLANCE

There are limited data on the risk of adverse effects of organotin compounds in humans.[153] The estimated tolerable daily intake (TDI) for bis(tri-*n*-butyltin) oxide was 0.25–5 μg/kg based on the most sensitive adverse effect (reduced lymphoid function, reduced lymphoid weight) in animal studies and a safety factor of 100.[154] The ADI for TPT compounds in Japan is 0.5 μg/kg body weight based on a 500-fold uncertainty factor and an LOAEL of 0.3 mg/kg body weight for increased mortality and reduced serum immunoglobulin in a 2-year rat study.[63]

The ACGIH derived an 8-hour TLV–TWA of 0.1 mg Sn/m^3 for organic tin to minimize the potential for adverse effects on immune function and the central nervous system.[101] The TLV–STEL of 0.2 mg Sn/m^3 was established to minimize eye and upper respiratory tract

irritation, headache, and nausea. Medical surveillance includes a comprehensive medical and work history with emphasis on the lungs, liver, kidneys, mucous membranes, allergies, and the central nervous system.[155] Table 31.5 lists the regulations and guidelines for organic tin exposures.

TREATMENT

Management of organotin toxicity is primarily supportive and preventative. There is a lack of clinical data to support the use of antidotes for the treatment of organotin poisoning. The administration of D-penicillamine did not increase urinary tin excretion in patients poisoned by trimethyltin.[3] BAL does not chelate organic metal compounds well. Animal studies suggest BAL[156] and meso-2,3-dimercaptosuccinic acid (DMSA)[157] may reduce the toxicity of dialkyltin compounds, but no data are available for humans. Plasmapheresis did not increase the tin elimination from workers poisoned with dimethyl and trimethyltin compounds.[112,118] Patients with triethyltin poisoning should be observed closely for the development of cerebral edema.

Chapter 32

TITANIUM

HISTORY

In 1791, Rev. William Gregor discovered titanium oxide in a mill stream in south Cornwall, England, near the parish of Manaccan. Four years later, the chemist, Martin Klaproth, named the metal after the giants in Greek mythology (Titans); he changed the name of the black iron titanium oxide ore from manaccanite to the current name of ilmenite.[1] In 1908, the French metallurgist, A.J. Rosii, discovered the dense opacity of a relatively pure titanium dioxide; however, commercial production of the white pigment did not begin until after World War I. Although the pure metal was not isolated until 1910, commercial production of metallic titanium did not begin until after World War II following the development of an economic purification process. Leventhal published the first paper on the use of titanium for orthopedic implants in 1951. Subsequently, an alloy containing 90% titanium, 6% aluminum, and 4% vanadium replaced elemental titanium commercially. Later, a variety of other titanium alloys became available as alternatives to replace aluminum and vanadium in this alloy; the metals included niobium, molybdenum, zirconium, iron, and tin; however, these later alloys demonstrate less strength than the original Ti–Al–Vd alloy.[2] Research on titanium dental implants began in the early 1950s with the first titanium implant recorded in 1964–1965.[3]

PHYSIOCHEMICAL PROPERTIES

Titanium (CAS RN: 7440-32-6, atomic mass: 47.87 g/mol) is an odorless, silver-gray metal that possesses both metallic and nonmetallic properties that are similar to silica and zirconium. Titanium is a member of Group 4 (Group IVb) of the periodic table along with hafnium and zirconium. Titanium is a transition element that combines with other metals (calcium, iron, potassium) to form alkyl and aryl titanate compounds; elemental Ti rapid forms a 1- to 2-nm oxide layer following air exposure that reduces reactivity and protects the metal from further redox reactions. The most common oxidation states are titanic (4+) and titanous compounds (3+); less common bivalent compounds (2+) and oxy-compounds (titanyl chloride) also exist. Titanic compounds easily hydrolyze to titanium dioxide (TiO_2). Naturally occurring TiO_2 exists in three crystalline structures: anatase, brookite, and rutile with the latter crystalline form being the most stable. Rutile TiO_2 is birefringent with refractive indices in the UV and visible wavelengths (i.e., suitable for sunscreens).

Metallic titanium is highly resistant to corrosion and water-insoluble. Titanium tetrachloride ($TiCl_4$) is a colorless, light-yellow liquid that is water-soluble at 20°C and decomposes in hot water, whereas other common titanium compounds (elemental titanium, titanium dioxide) are insoluble in cold water. $TiCl_4$ is a corrosive liquid that reacts with air to produce a dense white fume composed of solid, hydrolyzed titanium particles and a hydrogen chloride mist. In the presence of water, $TiCl_4$ undergoes a vigorous exothermic reaction yielding heat and hydrochloric acid. Titanium dioxide (TiO_2; CAS RN: 13463-67-7, MW 79.87) is a white crystalline solid that occurs in two primary forms (i.e., anatase and the more thermally stable, rutile). Organic titanium compounds are rarely used commercially.

EXPOSURE

Production Process

The major titanium ore is ilmenite (iron titanate, $FeTiO_3$, 53% TiO_2) with rutile ores (95–100% TiO_2) being much less abundant. Smelting ilmenite in an electric furnace produces titanium slag. The production process for TiO_2 previously involved the sulfate process; however, the chloride process using $TiCl_4$ as an intermediate is now more common. The treatment of titanium-containing ores in the presence of coke at high temperature (850–1,000 °C) releases $TiCl_4$. After the vaporized reaction, products are condensed and separated to produce pure $TiCl_4$; the oxidation of $TiCl_4$ under high temperature (1,200–1,370°C) and pure oxygen forms TiO_2. Chlorine gas is a by-product of this process that is recycled after separation from TiO_2. The primary particles are usually 0.2–0.3 μm in diameter; larger aggregates or agglomerates may appear. Ultrafine titanium dioxide has particle sizes in the range of 10–50 nm for use in sunscreens, catalysts, and plastics. These nanoparticles are typically coated with organic (e.g., esters, polyols, silanes, siloxanes) or inorganic (e.g., alumina, silica, zirconia) compounds to improve surface properties.

Uses

Because titanium is inert, corrosion-resistant, and 45% lighter than steel, this metal is a common constituent of welding rod coatings and alloys (e.g., Al, Sn, Mo, V) used in the aircraft and spacecraft industries. TiO_2 is the most common titanium compound (i.e., ~95% of titanium production); applications include constituents of white pigment and a coloring agent for many buildings and commercial and consumer products (e.g., teeth whiting). TiO_2 has replaced lead and zinc compounds as the white pigment in indoor paints; these pigments usually contain fine particles (i.e., >100 nm). Nanoscale TiO_2 particles (i.e., agglomerated particles <100 nm) are currently the most widely applied nanomaterial with various rods and shapes including anatase (7–10 nm), nanotubes (10–15 nm diameters × 70–150 nm length), and rutile (15–20 nm).[4] Applications of these nanoparticles range from sunscreens to cosmetic additives and surface coatings. Some of these nanoparticles produce inflammatory responses and reactive oxygen species in experimental studies; however, the exact properties and dose necessary to cause these effects remain unclear.[5] In a study of the nanoscale packing area of a plant producing TiO_2, the airborne particles range from 50 nm–several mm in diameter with 90% of the particles being <100 nm.[6]

TABLE 32.1. Commercial uses for titanium and titanium compounds. (Adapted from Valentin and Schaller).[7]

Substance	Uses
Elemental titanium (Ti)	Alloys, aerospace, chemical processing, dental amalgam
Titanium dioxide (TiO_2)	Pigments, paints, lacquers, printing ceramics, food additives, drug and cosmetic applications (nanoparticles)
Titanium tetrachloride ($TiCl_4$)	Polymerization (Ziegler type) catalyst, starting material for organic compounds
Titanous chloride ($TiCl_3$)	Polymerization catalyst
Organic titanium compounds	Cross-linking agents, catalysts

The ability of TiO_2 to effectively screen short-wave ultraviolet sunlight enhances its use in cosmetic products. Since the 1980s, TiO_2 and ZnO nanoparticles have been incorporated into sunscreens with the use of these nanoparticles becoming widespread by the 1990s. These formulations are highly effective UV radiation filters in transparent, light-textured products. The use of TiO_2 nanoparticle-dominated sunscreens requires the use of organic filters for broad-spectrum UV protection. Titanium is a constituent of dental amalgams. Table 32.1 lists common uses for titanium and titanium compounds.

Sources

Air

Ambient titanium concentrations in air are usually low (<0.1 μg/m^3) with concentrations ranging up to 0.5 μg/m^3 near industrial sources based on data collected before 1970.[8,9] Occupational Ti exposure results primarily from the inhalation of dust containing titanium production, particularly in the crushing and grinding of concentrates of rutile and the handling/production of $TiCl_4$.[10]

Soil

Titanium is the ninth most abundant metal in the earth's crust (i.e., 0.57% by mass). Typical Ti concentrations in soil average ~4.4% with a range of 0.3–10% titanium. Soils of the Canary Islands and the Hawaiian Islands particularly contain high Ti concentrations (i.e., up to 25%).

Water

Although data on the titanium concentration in water sources are limited, available data suggest that concentrations in water supplies average ~2 μg/L with a range up to 15 μg/L, whereas Ti concentrations in some rivers range up to 107 μg/L.[11]

Diet

Food represents the primary source of titanium in the diet with a very minor contributions from drinking water and ambient air. Relatively high titanium concentrations occur in butter, corn oil and margarine, integument, milled grains, condiments (ground black pepper, cloves), and lettuce, whereas whole grains, some vegetables, fruit, and most fish and meat contain little titanium.[12] In a duplicate food sample study, corn oil margarine contained 1.8 μg Ti/g, whereas fresh corn contained no detectable titanium. Titanium concentrations in meat ranged from 0.1 μg/g in beef chuck and lamb chops to 1.84 μg/g in pork chops. The daily intake of titanium averages ~300 μg with little titanium accumulation in the body based on long-term balance studies from the 1960s;[13] the mean titanium body burden averages ~15 mg.

DOSE EFFECT

Titanium is probably not an essential element. TiO_2 is practically nontoxic following ingestion. The older medical literature suggests the ingestion of 450 g TiO_2 is not associated with any toxicity.[14] Titanium and titanium compounds (oxides, peroxide, salicylate, tannate) demonstrate extremely low toxicity in animal studies, but little data are available in humans to correlate systemic effects with specific doses of titanium compounds.

TOXICOKINETICS

Although some titanium absorption occurs following ingestion, the amount of titanium and titanium compounds absorbed into the body is small (<3%). *In vitro* and *in vivo* human studies indicate nanoparticulate titanium dioxide is poorly absorbed by the gastrointestinal tract, similar to micron-sized particles.[15] The highest titanium concentrations typically occur in the lungs, particularly in miners, whereas the lowest Ti concentrations of titanium usually exist in the brain.[16] Titanium dioxide nanoparticles probably do not penetrate the dermis (stratum corneum) following skin application.[17] The biological half-life in humans is probably ~2 years based on animal studies.[18] Elimination of titanium occurs primarily by renal excretion; however, the role of biliary secretion of titanium into the intestines remains undefined.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The major finding on autopsies of workers exposed to fine titanium particles is Ti deposition in the lungs with little evidence of hyperplasia or fibrosis. Under light microscopy, titanium is birefringent and distinguishable from carbon. Moran et al. reported a series of six patients with birefringent foreign material and abundant black pigment in macrophages from various locations including fat, alveoli, and muscle.[19] X-ray analysis demonstrated the presence of titanium dioxide. Three of the patients had diffuse fibrosing interstitial pneumonitis with alveolar metaplastic changes and areas of bronchopneumonia; four patients died of sepsis. The source and amount of titanium exposure were not well defined. Postmortem examinations of drug addicts may demonstrate granulomatous reactions containing titanium and talc in the lungs, spleen, and liver.[20] A histological study of three workers exposed to titanium over 10 years revealed increased titanium deposition in the lungs along with cell necrosis and slight fibrosis;[21] however, co-exposure to silica, cigarette smoke, and tuberculosis could account for these changes and actual TiO_2 exposure was not reported. Other studies of lung tissue from titanium workers did not demonstrate evidence of pulmonary fibrosis despite large Ti deposits in the lungs.[22]

CLINICAL RESPONSE

Acute Toxicity

TiO_2 is practically nontoxic in ingestion as a result of very limited absorption by the gastrointestinal tract. Similarly, the bioavailability of TiO_2 nanoparticles appears low. In a study using gavage of rats with titanium dioxide nanoparticles, ICP/MS did not detect a significant increase in Ti concentrations in any tissues 24 hours after gavage including the small intestine, Peyer's patches, mesenteric lymph nodes, spleen, or liver; however, TEM demonstrated several nanoparticles in one cell from Peyer's patch.[23] Sections of the intestines did not reveal any nanoparticles.

Environmental Exposure

Environmental exposure to titanium is not typically associated with toxicity in the general population as a result of its relatively low elemental toxicity. Currently, TiO_2 is considered an inactive ingredient additive in human food. Titanium is a rare cause of hypersensitivity reactions in the general population; typically, adverse reactions to TiO_2 result from surgical or dental implants.[24] Despite relatively high Ti concentrations, these reactions usually develop in malfunctioning implants made of metals other than titanium. The clinical significance of type IV hypersensitivity reactions in relation to peri-implant reactions remains unresolved because cutaneous dendritic cells differ from antigen-presenting cells in deeper tissues.[25]

The European Scientific Committee on Consumer Safety considers the use of TiO_2 nanoparticles in dermal preparations are safe at concentrations up to 25%;[26] currently, there is no clear evidence that engineered nanomaterials including TiO_2 nanoparticles penetrate intact or inflamed skin and enter the systemic circulation.[27] Similarly, the Therapeutic Goods Administration concluded that current evidence supports the safe human use of sunscreens containing TiO_2 and ZnO nanoparticles.[28] Using immune-competent hairless mice, 36-week studies of weekly topical applications of TiO_2 and ZnO nanoparticle-containing sunscreens did not detect a statistically significant incidence of histologically diagnosed malignant or benign skin lesions in the UV-exposed groups compared with controls (no UVR, no sunscreen).[29] Few to no transcriptional lesions were found in the TiO_2- or ZnO-treated groups. Some elevation of hepatic Ti concentrations occurred in the TiO_2-treatment groups.

Occupational Exposure

Titanium Tetrachloride

$TiCl_4$ is extremely irritating to the skin, mucous membranes, and lungs. In the presence of water, $TiCl_4$ produces heat and hydrochloric acid. Two workers accidentally splashed with liquid $TiCl_4$ developed burns over ~20% of their bodies in areas where the liquid was in direct contact with their perspiration.[30] The burns were more severe than initially recognized on admission, resulting in grafting over the affected skin. Inhalations of this compound may cause chemical bronchitis or pneumonitis.[31] A large exposure to $TiCl_4$ was associated with the development of diffuse endobronchial polyposis that resolved within 1 year of exposure.[32]

Titanium Dioxide

TiO_2 is biologically inert; this compound probably does not possess fibrogenic properties following exposure to micron-sized particles.[11] Epidemiological studies generally support the lack of clinical effects including pulmonary fibrosis following such exposure.[33,34] A clinically significant lung disease is uncommon in workers at plants producing titanium by the sulfate process.[35] A study of titanium production workers exposed to Ti concentrations of 0.2–2.8 mg/m^3 demonstrated a slight reduction of FEV_1. Pleural thickening occurred in 36 of 209 workers; however, asbestos exposure could not be eliminated as a cause of these findings.[36] A single case study associated the development of fibronodular pulmonary infiltrates with titanium exposure based on a positive lymphocyte transformation test.[37] This hypersensitivity lung disease, which was suggestive of sarcoid, occurred in an aluminum smelter worker following titanium exposure for 13 years; however, exposure to a variety of metallic fumes prevented the determination of a direct causal relationship between hypersensitivity pneumonitis and titanium exposure. Similarly, the development of pulmonary alveolar proteinosis in a painter, who did not wear respiratory protection while painting, was associated with very high titanium concentrations on lung biopsy.[38] The specific exposure of this heavy smoker was not well defined. A case report associated the development of bronchiolitis obliterans in a 58-year-old Taiwanese diabetic with a 3-month exposure to heated electrostatic polyester powder paint containing TiO_2 nanoparticles.[39] The powder paint contained highly crystalline titanium dioxide and silicon dioxide with particle sizes ranging from 100–300 nm (i.e., above the nanoparticle range). The lung biopsy contained similar particles.

Titanium Ethanolate

A case report associated a large, accidental exposure to titanium ethanolate and hydrogen chloride in a chemistry laboratory with the development of a metal fume-like syndrome including low-grade fever, dyspnea, myalgia headache, and fatigue.[40] The symptoms resolved within 24 hours without any complications or sequelae.

Reproduction

No data are available on the genetic effects of titanium; however, there is no experimental evidence to suggest that titanium is a teratogen.

Carcinogenesis

Neither the IARC nor the US National Toxicology Program lists titanium or titanium compounds as human carcinogens. The IARC categorizes TiO_2 as possibly carcinogenic to humans (Group 2B) with sufficient evidence of carcinogenicity in animals and inadequate evidence of carcinogenicity in humans; the particle size was not specified.[41] A lifetime (2-year) study of $B_6C_3F_1$ mice exposed to TiO_2 at concentrations of 0–250 mg/m^3 revealed unique squamous cell carcinomas only at Ti concentrations that saturated the normal pulmonary clearance mechanism.[42] No excess tumors occurred at concentrations five times higher than the current permissible exposure limits. Substantial interspecies, route, and sex differences occurred with intratracheal studies in hamster and female mice negative.[43,44]

Epidemiological studies on workers exposed to engineered nanomaterials including TiO_2 nanoparticles are very limited by short duration of nanoparticle use, resulting in few exposed individuals and relatively short exposures.[27] There is little epidemiological evidence that occupational exposure to titanium dioxide is carcinogenic including lung and kidney cancers;[45] however, none of the studies assessed the impact of particle size (fine or ultrafine) or the potential effect of the coating compounds on the risk of lung cancer. A study of 969 workers exposed to $TiCl_4$ between 1956 and 1985 did not demonstrate a statistically increased incidence of lung cancer or a dose-response relationship between exposure to $TiCl_4$ and lung cancer.[46] The statistical power of the study was sufficient to exclude a 3-fold increase in the risk of cancer. A retrospective cohort mortality study among 4,241 titanium dioxide workers employed for at least 6 months did not detect increased mortality from bladder cancer, lung cancer, or any other cause, when compared with the general US population.[47] Similarly, the standardized mortality ratio (SMR) for all causes including lung cancer was not elevated in a cohort of European titanium workers with median cumulative exposure of 1.98 mg/m^3/year (interquartile range, 0.26–6.88 mg/m^3/year).[48] Examination of individual cancers revealed a slightly increased lung cancer risk compared with the general population and a suggestive dose-response relationship but no overall excess risk for kidney cancer. The SMR for lung cancer was 1.23 (95% CI: 1.10–1.38) based on a fixed effects statistical model. The SMRs varied from 0.76 (95% CI: 0.39–1.32) in Finland to 1.51 (95% CI: 1.26–1.79) in Germany. The heterogeneity between countries was of borderline significance ($P = 0.05$). Evaluation of the data using a random effects model yielded a SMR of 1.19 (95% CI: 0.96–1.48).

A mortality study of 3,607 titanium dioxide production workers followed from 1935–2006 did not demonstrate any increased mortality from all malignant neoplasms (SMR = 0.93, 95% CI: 0.82–1.06) or lung cancer (SMR = 0.98, 95% CI: 0.78–1.21).[49] Poisson regression modeling did not detect any significant trends with increasing exposure. A meta-analysis of 24,312 TiO_2 production workers from three industry-based cohort mortality studies using Cox regression coefficients for exposure-response models derived from random effects modeling did not demonstrate clear evidence of an association between occupational TiO_2 exposure and lung cancer.[50] The summary standardized mortality ratios were 1.10 (95% CI: 0.91–1.32) for lung cancer mortality and 0.92 (95% CI: 0.82–1.03) for all-cancer mortality.

Case-control studies do not indicate an increased risk for either lung or kidney cancer. A population-based, case-control study of 484 patients with bladder cancer suggested a weak association with titanium dioxide among several other occupations and chemicals;[51] however, other studies have not detected a similar association. In a case-control study of 857 cases of lung cancer, 33 cases and 43 referents were classified as exposed to titanium dioxide.[52] The odds ratio for lung cancer was 0.9 (95% CI: 0.5–1.5) with no apparent trend for increasing dose or frequency. The odds ratio for lung cancer following medium to high exposure for at least 5 years was 1.0 (95% CI: 0.3–2.7).

DIAGNOSTIC TESTING

SI Conversion Units

1 μmol/L = 47.87 μg/L
1 μg/L = 0.02089 μmol/L

Analytical Methods

The use of high-temperature reducing flame is important to increase the sensitivity of analytical methods because titanium poorly atomizes.[10] Atomic absorption spectrometry (AAS) has a detection limit of ~0.07 μg Ti/m^3 for environmental samples, whereas the detection limit of x-ray florescence is ~0.011 μg Ti/m^3 and proton-induced x-ray emission spectrometry is 0.001 μg Ti in ambient air samples. The use of inductively coupled plasma/optical emission spectrometry (336.121 nm) after acid digestion allows the detection of titanium in food samples in the 2–7 μg/L (ppb) range.[53] The detection limit of neutron activation analysis is ~10 times lower (0.007 μg Ti/m^3) than the sensitivity of AAS. The

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. limits of detection and quantitation for Ti in biological samples using inductively coupled plasma/mass spectrometry (ICP/MS) are 0.9 μg/L and 1.8 μg/L, respectively.[54] Using ultrasonic nebulization and a desolvating membrane, the LLOQ for titanium in serum was 0.002 μg/mL as measured by ICP/MS.[55] The use of double-focusing sector field ICP/mass spectrometry or ICP/MS allows detection of serum titanium in the ng/L range.[56]

A range of polyatomic and isobaric interferences, particularly from ^{48}Ca, complicate the interpretation of studies using graphite furnace atomic absorption spectrometry (GF/AAS) and quadrupole inductively coupled plasma/mass spectrometry, resulting in overestimation of titanium concentration. Inductively coupled plasma/optical emission spectrometry (ICP/OES) uses emission lines from the analyte to avoid any specific analytical interferences. In an analysis of whole blood and serum samples from patients with hip replacements, the limit of detection for serum titanium at 336.1 nm was 0.6 μg/L with a limit of quantitation of 1.9 μg/L.[57]

Biomarkers

Titanium ions associate with plasma proteins, resulting in higher titanium concentrations in plasma and serum than in whole blood. In an analysis of 16 matched serum and whole blood samples, the average serum Ti concentration was 3.7 μg/L (range, 0.6–15.6 μg/L) compared with 2.2 μg/L (range, 0.5–9.0 μg/L) for whole blood as measured by inductively coupled plasma/optical emission spectrometry. Regression analysis indicated that the best fit for the whole blood concentration was 0.58 serum Ti + 0.12.

Blood

The typical baseline serum Ti concentration in humans without titanium implants is <1 μg/L, whereas values in patients with titanium hip and/or knee implants range from 2–6 μg/L.[58] In the older medical literature, the reported Ti concentrations were much higher. Eight patients underwent insertion of a proximally porous-coated modular titanium-alloy femoral stem with a cobalt-alloy femoral head and a titanium acetabular socket. The mean serum titanium concentrations peaked ~3 years after insertion at ~2.9 μg/L; at 10-year follow-up, the mean serum Ti was ~1.8 μg/L (18 times higher than baseline) as measured by high-resolution sector field/inductively coupled plasma/mass spectrometry.[59] All hip implants were well functioning. A cross-sectional study of 95 of 199 patients with well-functioning, unilateral titanium alloy implants reported median whole blood Ti concentrations of 1.2 μg/L (IQR: 1.0–1.5 μg/L, 95th percentile: 2.2 μg/L) and 1.7 μg/L (IQR: 1.4 μg/L, 95th percentile: 2.56 μg/L) for plasma Ti.[60] The mean implant time was 8.4 years with a range of 5.3–11.9 years. The analytical method was high resolution/inductively coupled plasma/mass spectrometry with a limit of detection of 0.77 μg/L. The Ti concentrations were not correlated to the UCLA activity scale. In a retrospective cross-sectional study of titanium concentrations in 67 patients with total hip arthroplasty using modular neck titanium implants, the mean serum titanium concentration was 3.0 μg/L (range, 0.8–21.0 μg/L) compared with 0.9 μg/L (range, 0.1–4.5 μg/L) in 23 controls without implants.[61] The mean follow-up at the time of blood sample collection was 9 years (range, 7–13 years); complications were not reported.

In a study of Ti concentrations in eight patients with failed titanium alloy cementless total knee arthroplasties, the serum Ti concentrations were substantially higher than controls.[62] The mean serum Ti concentration in 21 patients with loose prostheses containing femoral stems composed of a titanium–aluminum–vanadium alloy was 8.08 μg/L (range, <2.11–17.2 μg/L) compared with 4.10 μg/L (range, <2.11–7.92 μg/L) in 21 controls (no implants) and 4.42 μg/L (range, <2.11–7.05 μg/L) in 12 patients with similar, normal-functioning prostheses. The analytical method was graphite furnace Zeeman atomic absorption spectrometry.

Urine

In a pooled urine sample from the general population and hospitalized patients collected in the 1950s, the Ti concentration averaged ~10 μg/L as measured by spectrographic analysis of ashed samples.[63] This value differed substantially from later studies using more sensitive analytical methods. The mean Ti concentration in urine samples from 20 controls and 17 dental health care workers without occupational Ti exposure was ~1,100 μg/L (maximum = ~2,000 μg/L) with no statistically significant difference between the workers and the control group.

HEALTH SURVEILLANCE

Titanium dioxide is the only titanium compound with exposure standards. The US OSHA PEL-TWA for TiO_2 is 15 mg/m^3. The recommended NIOSH REL-TWA guideline for exposure to airborne respirable TiO_2 pigment particles is 2.4 mg/m^3 compared with 0.3 mg/m^3

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for nanoscale TiO_2 particles. The ACGIH recommends a TLV–TWA of 10 mg/m^3 to maintain normal pulmonary clearance and minimize the potential for respiratory tract irritation.[64] There are no commonly accepted biological exposure indices for titanium or titanium compounds; urine is probably the most suitable specimen for evaluating Ti exposure.

TREATMENT

Treatment is supportive. $TiCl_4$ is an acid-corrosive that requires immediate removal from the eye. Excess liquid should be wiped away; then, the eye should be irrigated because the combination of moisture and $TiCl_4$ causes an exothermic reaction. Any solid particles of $TiCl_4$ should be removed from the eye, and the eye should be irrigated copiously for 30 minutes. All symptomatic patients following exposure to liquid $TiCl_4$ should have an ophthalmology consultation. Serious eye injuries require mydriatic agents, topical antibiotics, topical steroids, and ascorbate under the direction of an ophthalmologist.[65]

TiO_2 is poorly absorbed from the gastrointestinal tract; therefore, the decision to use decontamination measures depends on the ingestion of other substances that require decontamination measures. Inhalation of $TiCl_4$ may produce irritation of the lungs. Measures to evaluate lung function (ABGs, pulse oximeters, chest x-rays, pulmonary function tests) should be performed as indicated by the clinical condition of the patient.

Chapter 33

TUNGSTEN

HISTORY

The Swedish chemist Axel Fredrik Cronstedt discovered tungsten in 1758, naming the mineral tungsten (Swedish for heavy stone); Carl Wilhelm Scheele first discovered tungsten in the form of tungsten trioxide in 1781; however, he was unable to isolate the element. Two years later, the Spanish chemists Jose and Fausto de Elhuyar isolated tungsten after reducing tungstic acid in wolframite ore. In the early 1900s, the oral administration of tungsten power (25–80 g) as a substitute for barium during radiographic examinations was administered without observed adverse effects.[1] Hard metal is a powder metallurgy process that combines tungsten carbide with cobalt as a binder. The hard metal industry began in Germany after World War I with the development of armaments, radiotherapy screens, and cutting edges for dies, tools, and drills. In the 1940s and 1950s, case reports and case series documented an excess of respiratory abnormalities in workers with prolonged exposure to dusts from the grinding and processing of hard metal including cough, sputum production, bronchitis, bronchospasm, emphysema, and pulmonary fibrosis. Although symptoms were mild in most workers, a few developed severe pulmonary fibrosis and respiratory insufficiency. Bech et al. described six hard metalworkers with mild respiratory changes suggestive of early pulmonary fibrosis; he used the term, *hard metal disease* to denote the pulmonary abnormalities of workers exposed to dust from hard metal processes.[2] Animal studies in the 1950s suggested tungsten was relatively benign, whereas cobalt was intensely irritating to lung tissue, particularly when combined with tungsten carbide.[3,4] Bronchoprovocation tests of hard metalworkers in the 1980s implicated cobalt as the cause of hard metal-induced asthma rather than tungsten.[5] In the late 1990s and early 2000s, clusters of acute lymphocytic leukemia developed in children in Fallon, NV (16 cases), Elk Grove, CA (6 cases), and Sierra Vista, AZ (12 cases). The number of leukemia cases far exceeded the national incidence of this disease. All three of these clusters occurred in communities with active or inactive tungsten mines along with high natural tungsten concentrations in the soil as a result of environmental conditions (e.g., geothermal waters, evaporative concentrations in rivers, and precipitation of tungsten-containing minerals in sediment). Although tungsten concentrations in drinking water and urine of the children of Fallon were substantially higher than typical background concentrations, there was no dose-response or clear causal relationship between tungsten concentrations and the development of acute lymphocytic leukemia.[6]

PHYSIOCHEMICAL PROPERTIES

Tungsten (wolfram, W) is a hard, brittle, grayish-white, transition metal that belongs to Group 6 (Group VIB) of the periodic table along with seaborgium (a synthetic radioactive element produced by nuclear bombardment), molybdenum, and chromium. Elemental tungsten is highly resistant to acids and oxidation in air at ambient temperatures; however, above 400°C tungsten oxidation occurs. Being extremely dense (specific gravity = 19.3), tungsten has the highest melting point

(3,410°C) of all elements with the exception of carbon, the lowest coefficient of expansion (4.5×10^{-6}/°C), and the lowest vapor pressure of all metals along with good thermal and electrical conductivity. Pure polycrystalline tungsten is brittle; therefore, tungsten alloys contain transition metals (cobalt, nickel) to improve tensile properties and mold the metal to the shape required for commercial applications. Additionally, tungsten has the highest tensile strength at temperatures of >1,650°C. Tungsten is a good electron conductor.[7] Tungsten carbonyl is volatile (vapor pressure 0.1 mmHg at 20°C), whereas tungsten hexafluoride is a gas at room temperature.

Hexavalent is the highest and most stable tungsten oxidation state in the environment with lower valence states being relatively unstable; oxidation states range from 2− to 6+. In nature, there are five stable isotopes: ^{180}W (0.12%), ^{182}W (26.5%), ^{183}W (14.3%), ^{184}W (30.6%), and ^{186}W (28.4%). Table 33.1 list the identifying information and physical properties of

TABLE 33.1. Identifying information and physical properties of elemental tungsten and tungsten salts.

Physical Characteristic	Tungsten	Tungsten Oxide	Tungsten Trioxide	Tungsten Carbide
Formula	W	WO_2	WO_3	WC
Synonym	Wolfram	Tungsten dioxide	Tungsten blue, tungstic oxide, tungstic acid, tungsten oxide	Tungsten monocarbide
CAS RN	7440-33-7	12036-22-5	1314-35-8	12070-12-1 (carbide), 11130-73-7 (monocarbide)
Valence	0	+4	+6	+4
Molecular weight (g/mol)	183.85	215.84	231.85	195.85
Color	Silver–gray to tin–white	Blue	Canary yellow	Gray
Physical state	Solid	Solid	Solid	Solid
Melting point (°C)	3,410	1,500–1,700 (decomposes)	1,472	2,785
Density (g/mL)	18.7–19.3 (20°C/4°C)	10.82 (calculated)	7.2	15.6
Odor	odorless	odorless	NA	NA
Water solubility (mg/L)	Insoluble	Insoluble	Insoluble	Insoluble (<0.1, 20°C)
Vapor pressure (mmHg)	1.97×10^{-7} at 2,327°C	NA	NA	7.5×10^{-3} at 3,204°C

Physical Characteristic	Tungsten Chloride	Tungsten Hexafluoride	Ammonium Paratungstate	Sodium Tungstate, Dihydrate
Formula	WCl_6	WF_6	$W_7H_{24}N_6O_{24}$	$W_2NaO_4 \cdot 2H_2O$
Synonym	Tungsten hexachloride	Tungsten fluoride	APT	Disodium tungstate, dihydrate; sodium tungsten oxide; tungstic acid, disodium salt, dihydrate
CAS RN	13283-01-7	7783-82-6	12028-06-7 (anhydrous)	10213-10-2 (dihydrate); 13472-45-2 (anhydrous)
Valence	+6	+6	+6	+6
Molecular weight (g/mol)	396.56	297.83	1779.16	329.85
Color	Purple	Colorless	White	White or colorless
Physical state	Solid	Gas	Solid	Solid
Melting point (°C)	275	2.3	NA	692
Density (g/mL)	3.52	12.173	NA	3.25
Water solubility (g/L)	Decomposes	Decomposes in water (60°C)	270.2 (soluble)	732 (very soluble, 21°C)
Vapor pressure (mmHg)	43 (215°C)	Gas at room temperature	NA	NA

elemental tungsten and common tungsten compounds. Tungstate shares a common tetrahedral structure with phosphate, vanadate, and molybdate along with insulin-like effects.[8]

The chemical properties of tungsten and molybdenum are similar; tungsten forms a variety of compounds with different stereochemistry and oxidation states (ammonium paratungstate, tungsten carbide, tungsten trioxide). Most of the commercial compounds involve the 6+ oxidation state, although other oxidation states (2+, 4+, 5+) also exist. The lower valence states are relatively unstable compared with hexavalent tungsten. This metal easily forms complexes (e.g., oxyhalides). Similar to molybdenum, tungsten is an amphoteric metal that readily polymerizes as an acid anhydride and condenses with other acids (e.g., phosphoric) to form heteropolyacids. In acid solutions, tungsten forms condensed complex ions of polytungstates (e.g., ammonium paratungstate hydrate, $(NH_4)_{10}(H_2W_{12}O_{42})\cdot 4H_2O$), whereas these tungsten species depolymerize in alkaline solutions at room temperature. Polymerization of tungstate anions begins in mildly alkaline solution and progresses as the pH decreases. In acidic solutions (pH = 4.0–5.9), sodium tungstate polymerizes to sodium paratungstate ($N_{10}W_{12}O_{41}$) and sodium metatungstate ($N_6W_{12}O_{39}$).[9] *In vitro* studies suggest a stable protective oxide layer forms on the surface of implanted tungsten in tissues when the pH is <7.4, whereas the presence of a pH of >7.4 facilitates the corrosion of tungsten implants.[10]

Insoluble tungsten compounds (i.e., <10 mg W/100 mL water) include tungsten carbide, carbonyl, oxide, silicide, and sulfide, as well as tungstic acid. The tungstate ion (WO_4^{2-}) is the most water-soluble and most frequently encountered tungsten compound in biological systems. Other water-soluble tungsten compounds (W^{5+}, W^{6+}) include the oxyhalides (chloride, fluoride, oxychloride).

Experience with implanted tungsten coils suggests that tungsten is biodegradable *in vivo* following prolonged implantation. In a study of 46 children following a mean of 39.3 months (range, 2–72 months) after intraarterial implantation of pure tungsten coils (99.9%) for embolization of aortopulmonary collaterals, radiographical examination of the coils demonstrated loss of radiopacity.[11] Approximately 60% of the coils were no longer visible within 2 years after implantation. Assuming a loss of visibility as a biomarker of complete biodegradation and an exponential trend in the reduction of radiopacity, the authors predicted that almost all of the coils would dissolve within 10 years.

EXPOSURE

Production Process

Tungsten typically does not occur in the earth as a free element; underground mines produce ores containing ~0.3–1.5% WO_3; benefaction facilities usually concentrate the content of WO_3 to 60–75% by gravity separation.[7] Tungsten miners are exposed to a variety of potential carcinogens including cigarette smoke, silica, radon, and diesel fumes, particularly exhaust from pre-2000 engines.[12] In the soil, tungsten exists almost exclusively as oxo-rich tungstate minerals including wolframite (iron-manganese tungstate, $(Fe,Mn)WO_4$), scheelite (calcium tungstate, $CaWO_4$), and less commonly ferberite (iron tungstate, $Fe\ WO_4$) and hubnerite (manganese tungstate, $MnWO_4$). Tungsten production typically involves the following: 1) reduction of tungsten trioxide with hydrogen or carbon; 2) aluminothermic reduction of tungsten trioxide; 3) hydrogen reduction of tungstic acid or the corresponding anhydride; or 4) hydrogenation of tungsten trioxide or ammonium paratungstate. Production of elemental tungsten results from the digestion and reduction of tungstate ores with ammonium paratungstate being the main intermediate. After pretreatment with acid leaching (hydrochloric acid) or roasting with soda ash in an autoclave (aqueous sodium carbonate at ~200°C and >11.9 atm), tungsten is extracted as sodium tungstate. A liquid ion-exchange process converts the sodium tungstate to ammonium tungstate; then, to crystalline ammonium paratungstate after evaporation of the solvent. Arsenic frequently coexists with tungsten in polymetallic sulfide ores (e.g., wolframite, scheelite).[13]

The stepwise reduction of ammonium paratungstate with hydrogen or carbon either in tube or in rotary furnaces produces tungsten metal powder. The mixing of finely powdered tungsten with carbon black in an electric furnace at high temperatures filled with hydrogen as a catalyst produces tungsten carbide. Tungsten carbide prepared from oxygen-containing tungsten compounds is also a source for the production of tungsten carbide. Cobalt-tungsten carbide hard metals are composites of metallic cobalt powder and tungsten carbide particles alone or in combination with other carbides. Typically, the tungsten carbide (WC, W_2C) concentration ranges from 50–97% with small amounts of other metallic carbides (chromium, molybdenum, nickel tantalum, titanium) along with 3–16% cobalt depending on the desired properties. Cobalt is a binding agent for tungsten carbide in wear-resistant tools formed from cemented (sintered) tungsten carbide. The manufacturing process consists of the following

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

three steps: 1) production of cobalt and tungsten carbide powders; 2) mixing, pressing into desired shape (pre-sintering), heating to 1,500°C (sintering); and 3) finishing sintered product into desired shape by grinding and sharpening. The highest exposure to dust from the production of hard metals occurs during step 2, particularly powder-processing operations. The smelting of wolframite concentrates with charcoal or coke in an electric arc furnace forms ferrotungsten, an alloying material in steel production.

Typical tungsten alloys used for military applications contain tungsten concentrations exceeding 90% by weight along with transition metals (nickel, cobalt, and/or iron). These alloys are formed by liquid-phase sintering as a result of combining elemental tungsten powder and small amounts of transition metals that are heated from 1,100–1,500°C. These temperatures exceed the melting points of the transition metals, but not tungsten. Consequently, this sintering process produces a two-phase microstructure consisting of nearly pure tungsten microparticles embedded in a solid matrix composed of tungsten and variable amounts of transition metals depending on the temperature of the process and the amount of transitional metals.

Uses

Tungsten uses include the following: tungsten carbide, 65%; alloy additives, 16%; elemental tungsten, 16%; and tungsten chemicals, 3%.[7] The addition of tungsten to ferrous and nonferrous alloys increases hardness and tensile strength. Consequently, tungsten possesses a prominent place in the space and nuclear industry as a result of the frequent presence of tungsten as a component of alloys (e.g., steel, hard metal). Heavy metal tungsten alloy-based munitions ("green bullets") are alternatives to depleted uranium and lead in military applications.[14] Typically, these munitions contain 91–93% tungsten in combination with 3–5% nickel and either 2–4% iron or 2–4% cobalt. Tungsten concentrations in shots for hunting waterfowl typically range from 20–70% along with bronze, iron, nickel, and tin, whereas kinetic-energy penetrators usually contain >90% tungsten.[15] In addition, cemented tungsten carbide has replaced diamonds in most applications requiring a hard surface (e.g., rock drills, high-speed tool bits, grinding wheels, cutting tools). Tungsten wires, electrodes, contacts are common constituents of electrical and electronic applications.

Elemental tungsten is an electron emitter, a connector for aluminum layers in semiconductors, and a component of welding electrodes (e.g., thoriated tungsten), turbine blades, X-ray and electron tubes, lasers, rocket nozzles, high-speed rotors (e.g., gyroscopes), counterbalance weights, and consumer products (golf clubs, fishing weights, hunting munitions, lamp/light bulb filaments).[16] Tungsten disulfide is a solid lubricant, whereas deposition of tungsten coatings involves carbonyl, chloride, and fluoride salts of tungsten. Tungsten compounds (e.g., oxides, sulfides, hexachloride) are stable catalysts for a variety of chemical processes. Uses for sodium tungstate include the fireproofing of textiles, manufacture of tungsten-based catalysts, and production of colorants for printing inks, cigarette filters, waxes, glasses, and textiles. In Zucker diabetic fatty rats and streptozotocin-induced diabetic rats, the administration of oral sodium tungstate reduces blood glucose concentrations by a mechanism independent of the insulin receptor.[17,18] Ammonium paratungstate is a precursor of high-purity tungsten oxides, tungsten, and tungsten carbide powders, whereas tungsten trioxide is a source of tungsten metal and tungsten carbide powders. Table 33.2 lists occupations with potential exposure to tungsten or tungsten compounds; actual exposure varies with changes in the composition of products, production processes, and improvements in ventilation. Sodium tungstate is an experimental drug for the treatment of diabetes and obesity.[19,20]

Sources

Environmental sources for tungsten include alloy fabrication, municipal waste combustion, ore processing,

and tungsten carbide production. Although limited data are available, the exposure of the general population to tungsten is probably very low. The daily intake of tungsten averaged ~10 μg in four health volunteers given controlled diets and followed for 5 days.[21]

Air

Windblown dusts release tungsten to the atmosphere in very low tungsten concentrations (<10 ng/m^3); the unusually high density of tungsten limits the dispersion of tungsten to nondetectable concentrations (<1.5 ng W/m^3) unless near industrial sources or related to fallout from tungsten-containing explosives.[16,22] Occupational exposure to respirable particles of tungsten primarily occurs in scheelite and wolframite milling operations and near powder metallurgy operations that utilize tungsten or hard metal.[23] Tungsten oxide fibers are by-products of the reduction stage of the raw material used to produce tungsten carbide.[24] Air sampling of particulate matter in six US cities (Cincinnati, Denver, St. Louis, Washington, Chicago, Philadelphia) during winter of 1969–1970 demonstrated average tungsten concentrations of ~1 μg/m^3 (range, 0.1–2 μg/m^3).[25] During the late 1970s, a study of particulate emissions from five copper smelters in Arizona demonstrated a mean tungsten concentration of 15 ± 2 ng/m^3 (0.015 ± 0.002 μg/m^3).[26] Analysis of emissions from the stack of coal-burning facilities demonstrated tungsten concentrations ranging up to ~23 μg/m^3.[27]

Soil

Tungsten is the 18th most abundant metal in the Earth's crust, with tungsten concentrations in surface soils usually <2.5 mg/kg dry weight, but some areas (e.g., Alaska) exceed 24 mg/kg.[27,28] Higher tungsten concentrations in soil occur near point sources of tungsten. In a study of soil during the Gulf War (1990–1991), maximum tungsten concentrations (126 mg/kg) occurred in surface soil (<5 cm) near the Saudi Arabian–Kuwait border.[29] In surface soil 300 km from the border, the tungsten concentration was 3.25 mg/kg. The dissolution of tungsten in soil caused acidification, whereas high tungsten concentrations (i.e., >1%) produced a reduction in soil microbes and an increase in the fungal biomass.

Water

Tungsten is not usually detectable in US surface water or groundwater, except near mineral formations containing tungsten. Tungsten concentrations in drinking water are usually <0.1 μg/L; however, areas with tungsten formation (Nahanni River Basin in Northwest Territories of Canada, Iceland) may have elevated tungsten concentrations in groundwater and surface water. A study of surface water and groundwater down to 60 m from the Ethiopian Rift Valley demonstrated a median tungsten concentration of 0.11 μg/L with a range of <0.002–3.81 μg/L.[30] Higher tungsten concentrations (i.e., up to ~550 μg/L) occurred in nearby lakes. In Fallon, Nevada, several studies were conducted in the early 2000s by the US Agency for Toxic Substances and Disease Registry because of concerns about tungsten concentrations in drinking water. The mean tungsten concentration in samples from 76 private and municipal water supplies was 19.9 μg/L.[6] In samples from the private residential wells, the mean tungsten concentration was 37.5 μg/L with a range of 0.25–337 μg/L. Only trace amounts of tungsten (i.e., ~0.1 μg/L) are typically present in seawater.[7]

Diet

There are few data on the amount of tungsten in food or the daily tungsten intake from the diet. The estimated daily tungsten intake of four healthy adults fed diets with variable amounts of calcium ranged from 8–13 μg.[21] In a study of Danish onions grown commercially without known contamination, the mean tungsten concentration was 16.7 μg/kg fresh weight (n = 64; range, 6.3–39 μg/kg).[31] Certain plants (e.g., tomatoes) may exclude tungsten, whereas other plants (e.g., eucalyptus trees, rye grass, and *Calluna vulgaris* or heather) accumulate tungsten.[32,33] In a study of trace elements in Italians, beverages contributed significantly to the daily tungsten intake.[34] Mean tungsten concentrations in common beverages were as follows: wine, 1.7 ± 1.4 μg/L; beer, 7.4 ± 6.5 μg/L; tea infusion, 0.31 ± 0.51 μg/L; instant coffee, 1.8 ± 0.3 μg/L; and mineral water, 1.1 ± 1.2 μg/L.

Environmental Fate

Tungsten is a lithophilic element that occurs primarily in terrestrial rather than atmospheric or aquatic environments with very low concentrations in air and water.

Air

In the atmosphere, tungsten exists in the particulate phase because of the low vapor pressure of tungsten and tungsten compounds with the exception of tungsten carbonyl and tungsten hexafluoride. Windblown dusts naturally contain tungsten; anthropogenic processes

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

may release tungsten into air including the production and use of tungsten carbide, processing of tungsten ore, and hard metal fabrication. There is no current evidence that insoluble or soluble particulate-phase tungsten reacts with carbon dioxide or other compounds in the atmosphere.[27]

Soil

Following distribution to soil, tungsten exists as either soluble ions (e.g., tungstate ion, WO_4^{2-}) or insoluble (e.g., tungsten trioxide) tungsten species. Potentially, tungsten can form soluble complexes with a variety of inorganic and organic ligands. Monomeric tungstate is stable only at pH ≥6.2; tungstate is the main soluble species in alkaline environments.[22] In acidic environments, polymerized tungstate species may predominate. Although tungsten hexacarbonyl may occur in gas from municipal landfills,[35] the presence of methylated tungsten and other organic tungsten species is not well-documented.

The mobility of tungsten in soil is low to moderate as a result of tungsten binding to clay minerals and organic matter based on *in vitro* studies of tungsten alloys.[36] The adsorption coefficient (Kd) for tungsten increases with decreasing pH; consequently, soil mobility of tungsten decreases in an acidic environment. Soluble tungsten compounds (e.g., tungstates) may leach into groundwater. There are inadequate data to determine the extent of conversion of tungsten between different anions and the bioavailability of tungsten in various forms to plants and animals; typically, the tungsten concentration in edible plants is low (i.e., <0.1 ppm).[37]

Water

Tungsten naturally enters waterways through erosion (i.e., weathering of rocks and soils) and anthropogenic sources (mining, tungsten manufacturing processes). Elemental tungsten and metal alloys occur in water as insoluble solids, whereas tungsten compounds exist as insoluble solids or ions adsorbed to suspended sediment. Dissolution of elemental tungsten in aqueous solution probably occurs through a stepwise anodic oxidation of the metal to the W^{6+} oxidation state through the formation of less stable, lower oxidation states (W^{3+}, W^{4+}, W^{5+}).[32] *In vitro* studies suggest that this dissolution is typically associated with a reduction of local pH and dissolved oxygen concentration in the presence of other metals (e.g., cobalt, iron, and nickel in ammunition-grade tungsten alloy).[36] The extent of tungsten dissolution into more soluble polytungstate ions also depends on the presence of these metals. Iron enhances the dissolution of tungsten, whereas cobalt reduces the rate and amount of dissolution. Under neutral, mildly alkaline conditions (i.e., pH >6.2), tungsten exists in water primarily as the soluble tungstate ion, whereas other polyanions predominate under acidic conditions. Tungsten easily forms complexes including heteropoly acids from phosphorous oxides (e.g., phosphotungstic acid), arsenic, silicon, and vanadium.[7] Tungsten also combines with a large number of organic ligands; however, there are few data on the extent of these ligands in water or soil.

DOSE EFFECT

The poor solubility of tungsten limits its toxicity. The administration of oral W doses of 25–80 g to patients as a substitute for barium in radiological studies did not produce observable toxic effects.[1] Based on animal studies, soluble tungsten compounds (e.g., sodium tungstate) are much more toxic following acute exposure than elemental tungsten and insoluble tungsten compounds.[38,39] Subchronic animal studies indicate tungsten carbide dust is relatively inert following intratracheal instillation[4] with elemental tungsten producing slightly more local inflammation compared with tungsten carbide.[40] Preclinical studies on repeated oral exposure of sodium tungstate indicate body weight reduction, and nephrotoxicity may occur at daily doses of 125–250 mg/kg; however, rodent studies with molybdate suggest rats and humans may handle tungstate differently.[41]

TOXICOKINETICS

Sparingly soluble tungsten compounds have limited *in vitro* bioavailability suggesting primarily fecal excretion after oral exposure, whereas soluble tungsten compounds (sodium tungstate, tungsten oxides) are absorbed following oral or pulmonary routes with excretion primarily via the kidney.[41] The dermal bioavailability of tungsten and tungsten compounds is very minimal.

Absorption

There are few data on the kinetics of tungsten in humans following inhalation or oral exposure. The gastrointestinal absorption of soluble tungsten (e.g., sodium tungstate) is rapid and relatively good (i.e., >50%) based on animal studies,[42] whereas the oral absorption of elemental tungsten and tungstic acid is low. *In vitro* studies of elemental tungsten particles using comprehensive

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

artificial gastric juice formulations (NIOSH, ASTM, USP) and static dissolution technique indicate limited gastrointestinal absorption of elemental tungsten as a result of the short residence time in the stomach and the relatively long mean dissolution half-times varying from 60 ± 2 days (NIOSH) to 381 ± 84 days (USP).[43] In a 5-day study of four healthy volunteers fed a controlled diet that included 10 μg W/day, the balance study indicated ~60% of the tungsten was adsorbed as measured by neutron activation analysis; the species of tungsten in the diet was not reported.[7,21] Animal studies with ^{187}W suggest the gastrointestinal tract does absorb substantial (40–50%) soluble tungsten compounds containing the tungstate ion (WO_4^{2-})[44] with peak plasma tungsten concentrations occurring ~1–4 hours after the oral gavage of rodents with sodium tungstate.[45]

Distribution

Following the absorption from the gastrointestinal tract, distribution of tungsten occurs relatively rapidly, primarily to the bone, spleen, liver, and kidneys.[46] In contrast to ingestion, the highest tungsten concentration appears in the lungs and kidney following inhalation of insoluble tungsten compounds (e.g., tungsten oxide).[47] In rats administered sodium tungstate, most serum tungsten (i.e., ~80%) is bound to albumin with little binding to transferrin as measured by size exclusion chromatography/inductively coupled plasma/mass spectrometry and matrix-assisted laser desorption ionization/time-of-flight analysis.[18] Biokinetic modeling based on animal studies suggests that the kinetics of tungsten are similar to those of uranium rather than molybdenum with total transfer from plasma to all destinations in ~17 days.[48] These models predict that ~75% of the tungsten leaving the plasma passes directly into the bladder with ~5% deposited in the kidneys. At least a few tenths of 1% of the absorbed tungsten is retained in bone for an extended period.

Elimination

Following ingestion, elimination of insoluble forms of tungsten occurs primarily in the feces. Excretion of absorbed tungsten occurs rapidly (1–2 days) in the urine with animal studies indicating an initial plasma elimination half-life of 2–4 hours for soluble forms of tungsten (sodium tungstate) based on a two-compartment model.[42,49] However, animal studies indicate that bone is a repository for tungsten with a biological half-life exceeding 3 years.[44]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Although molybdenum is an essential element for several enzymes (e.g., aldehyde oxidase, mitochondrial amidoxime reductase, nitrate reductase, sulfite oxidase, xanthine dehydrogenase) in human and animal eukaryotes, tungsten is an essential element only for prokaryotes (i.e., microscopic, single-cell organisms including anaerobic bacteria, and cyanobacteria), probably as a result of the lower reduction potential of tungsten compared with molybdenum.[50] Elemental tungsten is relatively inert with low toxicity; data associating tungsten with human toxicity involves alloys of tungsten including elements other than pure elemental tungsten.

Mechanism of Toxicity

Tungsten Carbide

Hard metal disease is a giant cell interstitial illness of workers exposed to dusts from the manufacturing or grinding of tungsten carbide-containing tools or drill;[51] however, this disease probably results from exposure to the cobalt binders in combination with tungsten carbide (see chapter on Cobalt) because animal studies indicate that tungsten is relatively inert.[3] Tungsten may enhance the toxic effects of cobalt on the lungs based on animal studies that demonstrate pulmonary fibrosis in rats following the intratracheal instillation of tungsten carbide and cobalt in combination, but not in rats exposed to tungsten carbide or cobalt alone.[52] *In vitro* radiotracer studies indicate that solubility of tungsten in hard metal dust in blood and lung tissue is very low compared with cobalt; however, the low affinity of tungsten for proteins results in relatively high mobility of dissolved tungsten.[53] Additionally, *in vitro* studies indicate that markedly high tungsten concentrations (60,500 μg/L compared with 0.4 μg/L in human serum) in culture medium for 12 days do not inhibit the growth of human fibroblasts, vascular smooth muscle, or endothelial cells on the tungsten coils.[54] In contrast, *in vitro* studies indicate the specific tungsten alloy (91% W, 6% Ni, 3% Co) produces large amounts of reactive oxygen species, local cytotoxicity, inhibition of caspase-3, and DNA damage.[55] Other tungsten alloys without cobalt do not cause similar cellular reactions.

Elemental Tungsten

There are no human studies demonstrating tungsten **alone** causes respiratory disease; the interstitial lung

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

disease associated with the cemented tungsten carbide industry probably results from the cobalt binders rather than exposure to tungsten.[56,57] Tungsten carbide is relatively inert with minimal reactivity with oxygen; however, *in vitro* studies indicate tungsten is a good electron conductor that may contribute to the formation of interstitial fibrosis by altering the ionic state of metallic cobalt, thereby increasing the cobalt solubility, the transfer of cobalt ions to the carbide surface with increased oxygen reduction, and the generation of active oxygen radicals.[58,59]

Histological examination of 10 rabbits implanted 4 months earlier with tungsten coils in their subclavian artery did not demonstrate inflammation in or near the subclavian artery.[60] Additionally, there was no evidence of degeneration or necrosis in the peri-subclavian fatty tissue and no lymphadenopathy along the subclavian artery. The explanted coils had massive corrosion; the mean serum tungsten concentration increased from 0.48 ng/mL at implantation to 14.6 ng/mL at explantation. In experimental studies, sodium tungstate antagonizes the metabolic action of molybdenum as a metal carrier for certain enzymes (xanthine oxidase, sulfite oxidase, aldehyde oxidase) in the body.[61] A high-tungsten and low-molybdenum diet reduces the activity of these molybdenum-dependent enzymes; however, the role of molybdenum in any toxicity related to tungsten is unclear, as small amounts of supplemental molybdenum reverse any tungsten-related effects in these animal models.[62] The presence of nickel or cobalt in tungsten alloys probably accounts for the development of dermatitis in tungsten carbide workers rather than any hypersensitivity to tungsten. Studies of metallic tungsten, tungsten carbide, and tungsten disulfide nanoparticles suggest these substances are relatively inert; however, exposure to tungsten carbide or tungsten disulfide may cause some oxidative stress.[63,64]

Pathological Changes

Retained tungsten may persist in tissues depending on a variety of factors including size, surface area, pH, oxygen tension, and duration of retention. Analyses of electrochemical equilibria data in aqueous solutions suggest a pH of <7.4 enhances the formation of protective oxide layers on the surface of tungsten particles (i.e., passivation), whereas alkaline environments (i.e., pH >7.4) facilitate corrosion of the particles.[65] Biopsies of lungs from workers with hard metal disease may demonstrate only tungsten carbide because of the greater cobalt solubility compared with tungsten solubility. Tungsten carbide is a constituent of coatings on cautery tips. A 44-year-old woman presented with radiographic findings suggestive of microcalcifications associated with ductal carcinoma *in situ*.[66] Twelve years earlier, she had a benign lump removed in the same area of her breast. Histological examination of core samples demonstrated small fragments of refractile, non-birefringent material with focal foreign body giant cell reactions and black granule-containing macrophages. Analysis of the material confirmed the presence primarily of tungsten and smaller amounts of calcium, carbon, oxygen, and sulfur. The authors concluded that the most likely source of this material was the tungsten carbon coating of a cautery tip left in the breast 12 years earlier.

Postmortem Examination

Postmortem examination of workers with hard metal pneumoconiosis indicates that tungsten remains detectable in the lung for extended periods of time following exposure to hard metal dust.[67]

CLINICAL RESPONSE

Acute Toxicity

Elemental and water-insoluble tungsten compounds have minimal physiological activity. Water-soluble tungsten compounds may cause gastrointestinal symptoms; however, these gastrointestinal effects are not well documented in the general population or the work environment. A 19-year-old recruit in a French artillery regiment drank 250 mL of a mixture of beer and wine that he rinsed in a hot 155 mm gun-barrel containing tungsten and other chemicals.[68] Shortly thereafter, he developed nausea, seizures, and obtundation followed by acute tubular necrosis and anuria. His renal failure gradually resolved without reported sequelae. Analysis of the drink by inductively coupled plasma (ICP)/emission spectrometry revealed very high concentrations of tungsten (1,540 mg/L) in the beverage; however, exposure to aromatic nitrogen compounds in this drink may have contributed to or caused toxicity. The species of tungsten was not reported. Clinical studies do not support the use of sodium tungstate as a pharmaceutical agent for weight loss.[69]

Environmental Exposure

An exploratory study of urine tungsten concentrations in 2,465 randomly selected participants in the 1999–2000 National Health and Nutrition Examination

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Survey (NHANES) suggested an association between urine tungsten concentrations and peripheral artery disease.[70] The adjusted odds ratio for peripheral artery disease comparing the 75th to the 25th percentile of patients based on the urine tungsten concentration was 2.25 (95% CI: 0.97–5.24). The results must be interpreted cautiously because of multiple comparisons (nine metals), the wide confidence interval that included zero, and the use of an estimated 25th percentile because 30% of the urine tungsten concentrations in the selected population were below the lower limit of quantitation.

Percutaneous coil embolism is a medical procedure that uses tungsten coils to occlude leaking blood vessels. Favorable properties of tungsten for this application included high radiopacity, thrombogenicity, and ease of use; however, prolonged use caused corrosion despite the purity of the tungsten (>99.9%). In a study of 21 patients with tungsten coils implanted for aneurysms and fistulas, the mean tungsten load was 220 mg (18.5 mg/kg) with a range of 50–520 mg (4.9–45 mg/kg).[71,72] As a result of corrosion of the tungsten coils, follow-up studies demonstrated elevated tungsten concentrations after implantation in some, but not all, of these patients.[73] Studies following these patients for up to 3 years did not report adverse effects from the elevated tungsten concentrations. No further adverse effects or clinical studies have been reported in the medical literature over the subsequent decade since the original studies were published.

Occupational Exposure

There are few data associating tungsten exposure alone with chronic diseases. Pneumoconioses probably do not develop in workers exposed only to elemental tungsten or insoluble tungsten compounds. A mortality study of 5,054 workers employed at a titanium dioxide plant for at least 6 months found mortality rates similar to the general population with no increased mortality from nonmalignant or malignant respiratory disease.[74]

Carcinogenesis

Human

Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program (NTP) lists elemental tungsten or tungsten compounds as carcinogenic in humans; however, the IARC lists cobalt metal with tungsten carbide as a probable human carcinogen (Group 2A). The NTP lists cobalt–tungsten carbide as reasonably anticipated to be a human carcinogen.

A childhood-leukemia cluster occurred in Fallon, Churchill County, Nevada, where a hard metal manufacturing facility is located. Airborne particulate samples collected by 10 portable, high-volume particulate air samplers in Fallon during March, April, and November demonstrated higher ambient air tungsten concentrations in Fallon compared with four nearby towns.[75] The samples contained tungsten and cobalt air concentrations reported as significantly (P = 0.001–0.002) higher in Fallon (range, tungsten = 0.1–40.9 ng/m^3; range, cobalt = 0.04–7.5 ng/m^3) than surrounding towns (range, tungsten = 0.02–0.16 ng/m^3; range, cobalt = 0.04–0.58 ng/m^3). The environmental tungsten concentrations in Fallon were over an order of magnitude below current workplace standards. Both arsenic and tungsten contaminated drinking water in Churchill County. In a study of 307 tap water samples from households in this area, the median total tungsten concentration was 2 ng/mL (mean = 26 ng/mL; range, <1–610 ng/mL), whereas the median total arsenic concentration was 27 ng/mL (mean = 93 ng/mL; range, <3–2,196 ng/mL).[76] A cross-sectional case comparison study found no relationship between leukemia occurrence and urinary tungsten concentrations.[77] Additionally, there was no statistically significant association (odds ratio = 0.78, P = 0.57) between tungsten exposure from drinking water and leukemia observed in a sample population from Churchill County, Nevada. The leukemia cluster at Fallon exhibited similar age and immunophenotype profiles as most childhood leukemia cohorts consistent with an infectious pattern affecting the timing and incidence of the cluster.[78]

Animal

In a study of male F344 rats implanted with 4 (110 mg) and 20 pellets (550 mg) of military weapons-grade tungsten alloy pellets (91.6% tungsten, 6% nickel, 2.9% cobalt) in their hind legs, all 92 rats developed high-grade pleomorphic rhabdomyosarcomas within 16–20 weeks that rapidly metastasized to the lungs.[15] All of the positive controls (280 mg nickel) also developed similar tumors that required euthanasia, but the rate of tumor development was slower in controls than in weapons-grade tungsten alloy tumors. No tumors occurred in the rats implanted with tantalum (negative control) within the 1-year study. In this study, the role of tungsten in the carcinogenic effect of tungsten alloy pellets was unclear because of the known carcinogenic effect of the intramuscular administration of nickel and cobalt. Subsequent rodent studies suggest differential species responses and synergy between the three-component tungsten alloys rather than tungsten

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

alone. A 24-month rodent study examined groups of 20 male B6C3F$_1$ mice implanted with pellets containing one or two metal components of military-grade tungsten ammunition in the quadriceps after using an identical amount of the biologically inert tantalum (Ta) to replace the remaining components.[79] Sarcomas developed in 20% (n = 4) of the CoTa-implanted mice, 5% (n = 1) of WCoTa-implanted mice, and 5% (n = 1) of the WTa-implanted mice. These values were substantial below 80% of F344 rats developing rhabdomyosarcomas in the previous study. Another 24-month study examined groups of 20 male B6C3F$_1$ mice demonstrated the formation of rhabdomyosarcomas in the quadriceps of the high-dose WNiCo group, but not in the WNiFe group.[80] In contrast to the rat model, the rhabdomyosarcomas in the WNiCo group did not metastasize or exhibit aggressive growth patterns.

Subsequent studies confirmed that the tungsten/nickel/cobalt alloy, but not specifically tungsten, is carcinogenic. In a study of male F344 rats implanted intramuscularly with pellets of tungsten/nickel/cobalt, tungsten/nickel/iron, or pure tungsten, metastatic rhabdomyosarcomas formed around only tungsten/nickel/cobalt pellets between 6 and 12 months; no tumors developed in the rats implanted with tungsten/nickel/iron, pure tungsten, or tantalum pellets (negative control).[81] Urine tungsten concentrations ranged up to ~2,000 ng/mL in the high-dose wing of the study. Examination of the pellets demonstrated progressive, deep corrosion in the tungsten/nickel/cobalt pellets, but not in the tungsten/nickel/iron or pure tungsten pellets. Microarray analysis of the tumors associated with the tungsten/nickel/cobalt pellets demonstrated significant changes in gene expression including upregulation of the biological process of the cell cycle and downregulation of those involved with muscle development and differentiation. An 8-month pilot study on sodium tungstate administration to streptozotocin-induced diabetic rats did not detect any pathological changes consistent with carcinogenicity.[82]

DIAGNOSTIC TESTING

SI Conversion Units

1 μmol/L = 183.8 μg/L
1 μg/L = 0.005440 μmol/L

Analytical Methods

Methods for the quantitation of tungsten in biological samples include inductively coupled plasma/atomic emission spectrometry (ICP/AES; LOD, 50 μg/L), inductively coupled plasma/mass spectrometry (ICP/MS; LOD, 0.02–0.3 μg/L) after pretreatment with nitric acid,[83] chelation ion chromatography (CIC) coupled with on-line detection by ICP/MS, neutron activation analysis (NAA; LOD, 5 ng/g), atomic absorption spectrometry (AAS), and UV/Visible spectroscopy (UV/VIS). The limits of detection for tungsten in urine samples using ICP/MS are about one to two orders of magnitude lower than AAS using both quadrupole (LOD, 0.36 ng/L) and sector field (LOD, 0.49 ng/L) instrumentation.[84] The use of ICP/MS without sample pretreatment allows detection of tungsten at 5 ng/mL (LLOQ, 10 ng/mL) with some matrix-related interferences.[85] High-pressure liquid chromatography/inductively coupled plasma/mass spectrometry coupled with specialized separation methods including matrix-assisted laser desorption ionization/time-of-flight, size exclusion chromatography, anion exchange chromatography, or electrospray ionization/mass spectrometry detection allows the speciation of tungsten biomolecule complexes (e.g., polyoxotungstates).[18,86]

Samples for ICP/AES and ICP/MS are typically wet-ashed with nitric acid at elevated temperatures and then diluted prior to analysis. Most analytical methods (e.g., ICP/AES, ICP/MS, Flame AAS, UV/VIS spectrophotometry, NAA) for determining tungsten in biological media are also applicable to the analysis of tungsten concentrations in environmental samples (e.g., soil, water, and air). Flame AAS is the NIOSH-recommended technique (Method 7074) for determining tungsten in air with detection limits of 50 μg of soluble tungsten (LLOQ, 0.25 mg/m^3) and 125 μg of insoluble tungsten per sample (LLOQ, 0.6 mg/m^3). Results reported for tungsten typically are total tungsten concentrations without speciation.

Biomarkers

Blood

General Population

In a study of 8 healthy and 16 untreated hypertensive volunteers during the 1970s, there was no statistically significant difference in the serum tungsten concentration between the 2 groups as measured by neutron activation analysis; however, there was wide variation in the tungsten concentrations between the healthy volunteers (mean = 5.8 ± 3.5 μg/L) and untreated hypertensive volunteers (mean = 11 ± 13 μg/L).[87] More recent studies indicate serum tungsten concentrations in blood samples

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Abbreviation: NA = not available.
[a] Months; [b]The other 8 of 14 patients in this series had normal whole blood tungsten concentrations that were reported as <0.7 μg/L; [c]95% CI range.

from the general population without occupational exposure to tungsten are typically <0.5–1 μg/L with serum tungsten concentrations slightly lower than whole blood tungsten concentrations.[88] The tungsten concentrations from 355 Swedish urban adolescents were above the limit of detection ($n = 355$, LOD = 0.04 μg/L) in 79% of the serum samples with a maximum of 1.8 μg/L, whereas only 7% of whole blood concentrations in this same group had detectable tungsten concentrations ($n = 326$, LOD = 0.2 μg/L) with a maximum of 0.94 μg/L.[89] Similarly, only 6% of the whole blood samples from 130 northern German residents contained tungsten concentrations above the LOD (0.011 μg/L) with an upper 95th percentile of 0.017 μg/L as measured by inductively coupled/plasma mass spectrometry with an octopole-based collision/reaction cell.[90] In an Italian study of urban residents from Umbria, the mean serum tungsten concentration was 0.15 ± 0.004 μg/L (range, 0.05–0.40 μg/L) with a 95th percentile of 0.26 μg/L as measured by sector field/inductively coupled/plasma mass spectrometry (LOD, ~0.005 μg/L).[91] The arithmetic mean serum tungsten concentration in 218 Calabrian residents was similar (0.12 ± 0.003 μg/L).

Tungsten Coil Implants

Human A study of 19 patients followed a mean of 40 months after endovascular embolization of the spermatic vein with tungsten coils, the whole blood tungsten concentrations ranged from <1.0–4.8 μg/L.[92] Serum tungsten concentrations may increase soon after implantation in patients with large tungsten loads. The serum tungsten concentration was 4.95 μg/L in a sample drawn 3 months after the implantation of 225 cm of tungsten spirals (Mechanical Detachable Spirals, Balt, Montmorency, France) for a dural fistula.[93]

In a series of 10 patients with tungsten coils inserted during aortic aneurysm surgery, the mean whole blood tungsten concentration was 8.4 μg/L (95% CI: 4.7–15.1 μg/L) compared with 0.44 μg/L (95% CI: 0.37–0.51 μg/L) for a control group matched for age and sex.[94] Table 33.3 lists the mean and range of tungsten concentrations in three studies of blood samples from patients with corroding tungsten coils.

Animal Animal studies confirm the occurrence of increased blood tungsten concentrations following the retention of tungsten-containing material (e.g., coils, stents, and bullets).[95] In a study of 10 New Zealand white rabbits receiving tungsten coil implants in their subclavian artery, the mean serum tungsten concentrations increased from 0.48 μg/L (range, 0.2–1.8 μg/mL) before implantation to 12.6 μg/L (range, 9.9–22.0 μg/L) 4 months after implantation. Despite corrosion of the tungsten coils and elevated serum tungsten concentration, there was no histological evidence of local toxicity (i.e., peri-subclavian fat) or damage to any organs (heart, kidney, liver, lung, pancreas, spleen).

Overdose

A 19-year-old military recruit was transferred from a respirator to a tertiary referral center after the ingestion of a tungsten-containing liquid. He was acidotic with mildly elevated serum hepatic aminotransferases and hyperkalemic with moderate renal dysfunction requiring dialysis.[96] Renal biopsy demonstrated acute tubular necrosis. He was extubated the day after admission; no other seizures occurred. In admission blood samples at the tertiary referral hospital, the serum creatine phosphokinase was 1,287 IU/L and the serum tungsten concentration was 4,960 μg/L. Screening with high-performance liquid chromatography/diode array spectrophotometric detection and gas chromatography/mass spectrometry did not detect any other intoxicants in the wine. Two other military recruits vomited after drinking the wine; they did not develop any other sequelae.[97]

[a] 95% CI range.

Urine

General Population

Typically, urine tungsten concentration in the general population without occupational tungsten exposure is <1 µg/L.[88] The mean tungsten concentration in 24-hour urine samples from 14 German adults without occupational exposure to tungsten was 0.21 ± 0.09 µg/L with a range of 0.10–0.32 µg/L as measured by inductively coupled plasma/mass spectrometry.[83] In a study of 34 Northern Italian adults (mean age, 61.4 ± 12.4 years), the mean urinary tungsten concentration was 0.08 µg/L (95% CI: 0.02–0.26 µg/L),[98] whereas the mean urine tungsten concentration in 50 randomly selected central Italian adults was 0.77 ± 0.80 µg/L as measured by sector field/ICP/MS.[84] The values for the latter group were not normally distributed (geometric mean = 0.052 µg/L; range, 0.009–0.410 µg/L). The geometric mean of urine tungsten in representative samples of the US population collected in 2009–2010 during the National Health and Nutrition Examination Survey (NHANES IV) was 0.081 µg/L (95% CI: 0.075–0.087 µg/L); the corresponding creatinine-corrected value was 0.086 µg/g creatinine (95% CI: 0.080–0.093 µg/g creatinine).[99] NHANES data indicate the mean urinary tungsten concentration in smokers (mean = 0.10 µg/L, 95% CI: 0.091–0.111) is significantly higher than nonsmokers (mean = 0.08 µg/L, 95% CI: 0.076–0.084).[100] The mean tungsten concentration in 496 urine samples selected from participants in the NHANES III study and collected from 1988–1994 was 1.92 µg/L (1.92 µg/g creatinine) for all ages and sexes.[101] The upper 95th percentile was 3.31 µg/L (2.83 µg/g creatinine) with an LOD = 0.3 µg/L. The specimens represented a broad spectrum of the population (all ages and both sexes), but the sampling was not randomized. In a group of healthy patients consuming a normal diet, daily urinary excretion of dietary tungsten ranged from 2–13 µg as measured by neutron activation analysis, whereas the mean daily urinary excretion of tungsten in hypertensive patients was about 35 µg.[87]

Urinary tungsten concentrations in the general population vary with local sources of tungsten. During an investigation of a cluster of childhood leukemia in Churchill County, Nevada, a cross-sectional study of urine tungsten concentrations in the community demonstrated a geometric mean of 1.19 µg/L (95% CI: 0.89–1.59 µg/L) compared with the US National Exposure Report reference mean of 0.08 µg/L (95% CI: 0.07–0.09 µg/L).[102] The former value reflected a relatively high tungsten concentration in Church Hill drinking water (GM = 4.66 µg/L; 95% CI: 2.98–7.30 µg/L).

Tungsten Coils

Most follow-up studies of patients with tungsten coils implanted for embolization therapy have elevated urine tungsten concentrations compared with the population without occupational tungsten exposure.[73] In a series of 10 patients with tungsten coils inserted during aortic aneurysm surgery, the urine tungsten concentrations ranged from 290–539 µg/L compared with <1 µg/L in 10 age- and sex-matched controls.[94] Table 33.4 lists the mean and range of tungsten concentrations in two studies of urine samples from patients with corroding tungsten coils.

Abnormalities

Tungsten is radiodense, resulting in the presence of opacities following retention in tissues. Abnormalities in serum chemistries are not typically associated with exposure to elemental tungsten or tungsten compounds.

HEALTH SURVEILLANCE

Environmental Monitoring

The US OSHA PEL–TWA for exposure to soluble tungsten compounds in the construction and shipyard industries is 1 mg W/m^3 with a STEL of 3 mg W/m^3. OSHA established a PEL–TWA of 5 mg W/m^3 for elemental tungsten and its insoluble compounds with a STEL of 10 mg W/m^3 to reduce the risk of pulmonary fibrosis from other dusts (e.g., cobalt). ACGIH has similar guidelines for tungsten exposure as demonstrated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 33.5. Guidelines and regulations for exposure to tungsten in workplace air.

Media	Value
	OSHA[a]
PEL–TWA (8-hour)[b]	5 mg W/m^3 (elemental/insoluble W)
	1 mg W/m^3 (soluble W)
	NIOSH
REL–TWA (10-hour)	1 mg W/m^3 (soluble W)
	5 mg W/m^3 (elemental W/insoluble W salts)
REL–STEL (15-minute)	3 mg W/m^3 (soluble W salts)
	10 mg W/m^3 (elemental W/ insoluble W salts)
	ACGIH
TLV–TWA (8-hour)	3 mg W/m^3 (elemental W/W salts)[c]

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; STEL = short-term exposure limit; TLV = threshold limit value; TLV–TWA = respirable particulate matter; TWA = time-weighted average.
These guidelines and regulations for exposure to tungsten and tungsten compounds assume these substances do not contain cobalt. For co-exposures to cobalt or nickel (e.g., tungsten carbide), separate guidelines and regulations apply, depending on cobalt and nickel concentrations nickel concentrations.
[a] In July 1992, the 11th Circuit Court of Appeals vacated PELs set by OSHA in 1989 for 212 substances including tungsten. Currently, OSHA does not have regulations for tungsten exposure except for the maritime and construction industries; [b]Shipyards, construction industries only; [c]As respirable particulate matter in absence of cobalt.

in Table 33.5. Analysis of data for the derivation of no-effect levels for tungsten compounds using criteria of the European Community Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) indicates derived no-effect levels (DNEL) for exposed workers similar to the above values. The long-term inhalation of DNEL for sodium tungstate (i.e., water-soluble tungsten compounds) was 1.3 mg Na_2WO_4/m^3 (1.7 mg W/m^3) compared with 7.3 mg WO_3/m^3 (5.8 mg W/m^3) for sparingly soluble tungsten compounds.[103] The World Health Organization has not issued any drinking water guidelines for tungsten.

Initial medical screening and annual medical examinations for workers directly exposed to soluble and insoluble tungsten compounds as well as elemental tungsten should include a chest X-ray and pulmonary function tests.

Biological Monitoring

Tungsten carbide and cobalt are the main constituents of hard metal alloys; these two metals are combined in the sintering process to form cemented carbides for composite materials in cutting and grinding tools. Multi-element analysis of biological specimens from workers with hard metal pneumoconiosis indicates that blood and urine tungsten concentrations do not correlate well to the presence of disease in affected workers.

The tungsten concentrations in biological media from hard metalworkers vary substantially between factories as a result of varying bioavailability and the variety of techniques used in the production of hard metal.[104]

Blood

In a study of Italian hard metalworkers (sintering, grinding, mold filling, manufacturing), blood and urine tungsten concentrations did not separate diseased workers from healthy workers with the tungsten concentrations in the diseased workers independent of age, duration of exposure, and tungsten dose.[105] The mean tungsten concentration in whole blood samples from 43 workers in this study was 1.2 ± 1.6 µg/L (range, 0.04–6.5 µg/L) with a median of 0.6 µg/L. In a study of 49 Italian workers in hard metal alloy industries, the geometric mean tungsten concentration in whole blood and plasma was 0.13 ± 2.20 µg/L and 0.18 ± 2.49 µg/L, respectively.[98] The highest blood tungsten concentrations occurred in 14 wet grinders (0.27 ± 1.83 µg/L and 0.46 ± 1.87 µg/L, respectively). A 37-year-old hard metal grinder developed hard metal disease while working at a small shop with poor ventilation; her admission blood tungsten concentration was 60 µg/L as measured by neutron activation analysis.[106] She had a restrictive lung defect and an eosinophilic interstitial fibrosis (BAL fluid, 30% eosinophils) that progressed to death 8 months later despite steroid use.

Urine

The mean tungsten concentration in urine samples from 78 Italian hard metalworkers was 6.7 ± 19.4 µg/L (range, 0.11–230 µg/L) with a median of 1.05 µg/L.[105] In a study of the hard metal manufacturing industry, the mean urinary tungsten concentration in 14 powder processing workers was 12.2 µg/g creatinine (95% CI: 8.0–16.5 µg/g creatinine) compared with 94.4 µg/g (95% CI: 11.2–177.5 µg/g creatinine) in 5 grinders.[107] The former were exposed primarily to tungsten metal, whereas the latter were exposed to tungstate (wet grinding) and tungsten oxide/carbide

(dry grinding). On a group basis, air tungsten concentrations did not correlate to urine tungsten concentrations, probably as a result of variations in solubility and bioavailability of tungsten compounds. The maximum tungsten concentration during ambient air monitoring was 417 μg/m^3 with four samples from powder processing area ranging from 177–254 μg/m^3 and ~81 μg/m^3 in a sample from the dry grinding area. In a study of 36 Italian workers in hard metal alloy industries, the geometric mean tungsten concentration in end-of-shift urine samples at the end of the week was 7.06 ± 4.46 μg/L.[98] There were substantial differences between urine tungsten values and different parts of the hard metal process. The highest mean urine tungsten concentration (20.49 ± 2.38 ng/mL) occurred in wet grinders ($n = 13$), whereas the lowest mean end-of-shift urine tungsten concentration was 1.11 ± 6.04 μg/L in sintering ($n = 6$). The latter process involves exposure to tungsten carbide (airborne tungsten = 0.13 μg/m^3, $n = 1$), whereas wet grinders were exposed to tungstate (airborne tungsten = 6.54 μg/m^3, $n = 1$). Limited air monitoring suggested tungsten exposure of these workers was below current occupational standards, with the exception of wet grinders. The article did not report any symptoms associated with these tungsten concentrations. In a German study of 52 workers in a hard metal producing and processing plant, the urine tungsten concentration (median, 30.5 μg/L; interquartile range, 14.5–57.7 μg/L) as measured by high-resolution/inductively coupled/plasma mass spectrometry correlated with the airborne tungsten concentration ranging from 0.12–0.21 mg/m^3.[108] There was no correlation between the tungsten concentration in ambient air or urine and the tungsten concentration in exhaled breath condensate.

A 37-year-old hard metal grinder developed fatal hard metal disease while working at a small shop with poor ventilation.[106] Three other workers at the shop remained asymptomatic. The authors noted that blood and urine tungsten concentrations did not accurately predict the clinical course of hard metal disease.

TREATMENT

The treatment of exposure to tungsten is supportive. Serious toxicity as a result of exposure to tungsten or tungsten compounds has not been well-described. Decontamination measures following exposure to soluble tungsten compounds may be appropriate within the first 1–2 hours after exposure, but these measures are probably not necessary for exposures to elemental tungsten or insoluble tungsten compounds. There are few data on the efficacy of chelating agents following tungsten exposure; limited animal studies do not support the use of DMSA following large exposures to sodium tungstate.[109]

Chapter 34

VANADIUM

HISTORY

The Spanish mineralogist del Rio first discovered vanadium (V) in 1813; he gave this element the name *panchromium* because of the color changes that occur during the transition of elemental vanadium to various oxidation states.[1] Nils Sefstrom purified vanadium in the oxide form during 1831; he named the compound after the Norse goddess of youth, love, beauty, and the dead, Vanadis (Freja, wife of Oden). Because of their hardness and ability to form alloys, vanadium-containing alloys (e.g., ferrovanadium) became popular components of hard steel alloys used in machines and tools. In 1911, Dutton first reported the development of dry cough and irritation of the eyes following occupational exposure to the fumes and dusts of vanadium oxide.[2] Case series in the 1930s and 1940s document the occurrence of conjunctivitis, rhinitis, sore throat, and cough following occupational exposure to vanadium pentoxide.[3,4] Although the use of vanadium compounds to treat syphilis and leishmaniasis was recommended in the 1920s and 1930s,[5] the medicinal use of vanadium preparations has been rare.

As the use (e.g., mordant in dyeing, catalyzer in chemical industry, accelerator for the drying of paint) of vanadium compounds expanded in the 1940s and 1950s, case reports associated exposure to vanadium dusts with greenish-black discoloration of the tongue and irritation of the skin, mucous membranes, and respiratory tract.[6,7] Workers developed vanadium poisoning while cleaning oil- or gas-fired boilers because vanadium is a natural component of fuel oils. Vanadium probably corrodes the oil-heated boilers by catalyzing the oxidation of sulfur dioxide to sulfur trioxide.[8] A vanadium-deficiency disease has not been defined in humans; however, vanadium is a prime candidate for essential status, in part because vanadium occupies position 25 in the periodic table. This position is near the positions (23–34) of the most essential trace elements in the periodic table. Haloperoxidases were the first vanadium-containing enzymes discovered in 1984.[9]

PHYSIOCHEMICAL PROPERTIES

Vanadium (V) is a transitional metal that is a member of the first transition series of the periodic table Group 5 (Group VB) that includes niobium, proactinium, and tantalum. Tables 34.1 and 34.2 list identifying information on elemental vanadium and vanadium compounds. Elemental vanadium is a soft, silvery-gray, nonvolatile, refractory (high-melting point) element that reacts with oxygen, nitrogen, and carbon to form oxidation states varying from 1− to 5+; the most common valences are +3, +4, and +5. Elemental vanadium does not occur naturally. This metal oxidizes easily above temperatures of >660°C forming brownish-black trioxide, blue-black tetroxide, or reddish-orange pentoxide depending on the temperature.

The most stable oxidation state is the quadrivalent salt (VO^{2+}, vanadyl). Trivalent vanadium (V_2O_3) is a strong reducing agent that dissolves in acid to form a green hexa-aquo ion. Pentavalent salts include metavanadate (VO_3^-), orthovanadate ($H_2VO_4^-$), and pyrovanadate ($V_2O_7^{4-}$). The metavanadate form is the most common state in extracellular body fluids, whereas

TABLE 34.2. Physiochemical data for vanadium and vanadium compounds. (Adapted from Table 3.2, Agency for Toxic Substances and Disease Control).[10]

Compound	Molecular Weight (g/mol)	Color	Density (g/mL)	Melting Point (°C)	Water Solubility (g/L)
Vanadium	50.94	Light gray or white luster	6.11 (18.7 °C)	1880–1900	Insoluble
Vanadium pentoxide	181.88	Yellow to rust brown crystals	3.36 (18 °C)	690	8
Vanadyl sulfate	163	Blue powder	No data	No data	Soluble
Sodium metavanadate	121.93	Colorless crystals	No data	No data	211 (25 °C) 388 (75 °C)
Sodium orthovanadate	183.91	Colorless	No data	850–856	Soluble
Ammonium metavanadate	116.98	White-yellow crystals	2.33 (20 °C)	200 (decomposes)	Slightly soluble

the quadrivalent form predominates intracellularly.[11] Vanadium pentoxide is the most common commercial and environmental form of vanadium; this compound exists as a yellowish to red-brown crystalline powder that is sparingly soluble in water. There are few data on the odor-warning properties of vanadium compounds; VCl_4 and VCl_3 may release a pungent odor (i.e., Cl_2) following decomposition at room temperature.

Like molybdenum, vanadium participates in biological processes in both anionic (vanadates) and cationic (VO^{2+}) forms. The chemical reactions of the former resemble phosphate, whereas the latter behaves as complexes in coordination to biogenic ligands and compounds similar to other transition metal ions. Below pH 3.5, vanadium exists as vanadyl (VO^{2+}). In basic solutions, vanadium exists as orthovanadate (VO_4^{-3}), which is chemically similar to phosphates (PO_4^{3}).[12] Neutral solutions contain vanadium primarily as $H_2VO_4^-$. In high concentrations, vanadium polymerization occurs; the tetramer ($V_4O_{12}^{4-}$) form is the main polymer in these solutions.[13] Further polymerization can produce an isopolyanion, $V_{10}O_{28}^{6-}$. The chemical similarity of vanadium to phosphorus helps explain the effect of vanadium on phosphorylation reactions in the body. Some VO_3^- enter cells via anion transport systems where glutathione reduces pentavalent vanadate to quadravalent vanadyl. Vanadyl is relatively nonreactive as a result of its complexing with proteins and other small molecules. Vanadium generally does not combine with organic compounds. Synthetic vanadium compounds are experimental drugs for the treatment of diabetes (vanadyl acetylacetonate, bis(maltolato)oxyvanadium (IV), the ethylmaltol analog, bis(ethylmaltolato)oxyvanadium (IV)),[14] and cancer (vanadyl sulfate).[15]

EXPOSURE

Production Processes

Commercial vanadium-containing ores include carnotite (potassium uranyl vanadate), patronite (impure vanadium sulfide), roscoelite [$K(V^{3+}, Al, Mg)_2AlSi_3O_{10}(OH)_2$], vanadinite [$Pb_5(VO_4)_3Cl$], and phosphate rock.[16] Sources in the United States include uranium-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

bearing minerals in Colorado and some Western US phosphatic shales and phosphate rocks. Extraction methods for elemental vanadium in these ores involve calcium reduction, electrolytic refining, solvent extraction from uranium ores, and thermal decomposition. Extraction of some of these ores produces vanadium-rich alloy (e.g., ferrovanadium).[17] Other sources of vanadium include crude petroleum deposits (e.g., Venezuelan crude oil),[8] slag from the production of ferrous alloys, and by-products of the processing of some nonferrous ores (aluminum, titanium, uranium). After these vanadium-containing materials are crushed, dried, and finely ground, sodium salts are added to produce sodium metavanadate ($NaVO_3$) during the roasting process. The mixing of sulfuric acid with sodium metavanadate produces a precipitate that dries in the form of vanadium pentoxide. High vanadium concentrations (i.e., up to 50%) occur in flue-gas deposits from oil-fired furnaces, particularly oil from Iraq, Iran, Kuwait, Venezuela, and the Mexican Gulf. Petroleum from the United States generally contains very small amounts of vanadium.[18]

Uses

Uses of vanadium include the following: 1) production of steel and nonferrous alloys for ball bearings, springs, and automobile parts; 2) catalyst for the production of sulfuric acid and the conversion of naphthalene to phthalic anhydride during the formation of plastic; 3) manufacturing of semiconductors, photographic developers, and coloring agents; 4) production of brown to green colors in ceramics; and 5) ferrous alloys for aircraft engines. Of these uses, ferrovanadium as a steel additive accounts for ~80% of vanadium production, particularly in rust-resistant and high-speed tool steels.[16] Vanadium pentoxide provides ultraviolet-filtering properties in some forms of glass. Pure vanadium seldom is the preferred industrial form of vanadium because elemental vanadium readily reacts with carbon, nitrogen, and oxygen at temperatures above 300 °C. The vast majority of vanadium is used as ferrovanadium or vanadium carbide in the production of high-resistance carbon steels. The addition of the vanadium compounds improves the hardness, malleability, and fatigue resistance of the steel. Nonferrous alloys containing vanadium are used in jet aircraft, space technology, and the atomic energy industry. Important applications of vanadium oxides and vanadates as catalysts include the following processes: petroleum cracking, purification of exhaust gases, and the oxidation of ethanol. Vanadium is a constituent of scale dust from boilers burning V-containing crude oil. Samples of scale dust may contain 5–15% vanadium pentoxide as well as other compounds (e.g., calcium oxide, copper, iron oxide, nickel oxide, potassium oxide, sodium oxide, silica, sulfate, phosphate).[19] Elemental vanadium, sodium metavanadate, and vanadyl sulfate are constituents of some commercial supplements including weight-training supplements and multivitamins.

Sources

Air

Exposure of the general population to vanadium *in air* results primarily from the combustion of petroleum, coal, and heavy oils during the generation of electricity and heat. During the burning of oil fields in Kuwait, air particulate matter in Bahrain contained 11–42 ng V/m^3.[20] Vanadium concentrations in coal, crude oil, and carbon fossils average ~15–100 μg/g (ppm), 600 μg/g (ppm), and 1,500 μg/g (ppm), respectively.[21] Vanadium is usually the most abundant trace metal present in petroleum. Vanadyl ion (VO^{2+}) in the form of organometallic complexed with porphyrins is the most common form of vanadium in petroleum as measured by high-resolution continuum source/atomic absorption spectometry with a graphite furnace or conventional electrothermal/atomic absorption spectrometry.[22] Natural gas contains very small amounts of vanadium (<0.05 ppm). Additional industrial sources of vanadium in the metallurgy industry include discharges from furnaces roasting vanadium slag, vanadium pentoxide smelting furnaces, and crucibles that melt ferrovanadium alloys. Anthropogenic sources account for ~$^2/_3$ of the atmospheric vanadium (i.e., vanadium oxides), particularly from residual fuel oils (1–1,400 ppm).[16] Continental dust, marine aerosols, and, to a lesser extent, volcanic emissions account for the rest of the vanadium in the atmosphere.

Ambient air concentrations of vanadium typically are low depending in part on urbanization and industrialization. Marked seasonal and geographic variation occurs in the ambient concentration of vanadium. These variations result from climatic conditions (e.g., cold weather, atmospheric inversions) and the burning of residual fuel oils during the production of electricity and heat. In 1973, the highest vanadium concentrations in the United States occurred in the northeast where the consumption of fossil fuel during the production of electricity and heat was high. The median vanadium concentration in these cities was 620 ng/m^3 (range, 150–1,400 ng V/m^3) compared with a mean of 11 ng/m^3 in other urban areas.[23] The concentration of vanadium

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in ambient air in rural areas is usually much lower than in urban areas. Typically, the vanadium concentration ranges from 1–2 ng/m^3 in *remote* rural areas to 50–60 ng V/m^3 in rural areas with sources of vanadium.[16] In a 3-year sampling period in southeast Chicago and east St. Louis, Illinois, average vanadium concentration of fine particles (<2.5 μm) in inhalable particulate matter was 3.0 ng/m^3, whereas the mean vanadium concentration in coarse particles (2.5–10 μm) was 3.7 ng/m^3 and 3.0 ng/m^3, respectively.[24] Average vanadium concentrations in fine and coarse particulate matter collected from a rural site (Bondville, Illinois) were 0.8 ng/m^3 and 1.2 ng/m^3, respectively. In sampling ($PM_{2.5}$ fraction) from rural Vermont, the geometric mean seasonal vanadium concentration was 0.82 ng/m^3 with maxima occurring during the winter and spring months and minimum concentrations observed during the summer months.[25] The authors attributed the variation to the operation of northeastern oil-fueled power plants based on factor analysis. Average vanadium concentrations in air samples collected from a rural forest in Denmark ranged from 11.5 ng/m^3 in 1979 to 4.4 ng/m^3 in the early 2000s.[26] Emissions from adjacent European cities contributed to the vanadium load.

Soil

Vanadium is a widely distributed trace metal that is the 22nd most abundant element in the earth's crust with an average concentration of ~100 mg/kg (ppm) in soil; vanadium concentrations in typical soil are similar to nickel and zinc. The actual content of vanadium depends on the type of parent rock. The soil types that contain the highest concentration of vanadium are tundra podzols and clays. Elemental vanadium does not exist in nature because of its propensity to react with other elements, particularly oxygen.[16] The largest releases of vanadium to the soil result from the weathering of rocks rather than from anthropogenic sources (e.g., super-phosphate fertilizers, 0.05–2 g V/kg; basic slag, 1–5 g V/kg).[27] Basic rocks contain higher vanadium concentrations compared with neutral and acidic rocks. The bioavailability of vanadium in soil is limited because of the binding of vanadium to soil.[28]

Water

In water, vanadium is converted from trivalent to pentavalent oxidation state. Natural releases of vanadium from the erosion of soil and the weathering of rock far exceed the deposition of vanadium from anthropogenic sources in the air. The former process involves the release of vanadium into water following the conversion of the less water-soluble trivalent form to the more water-soluble pentavalent form. Most samples from drinking water supplies contain levels of vanadium below detectable limits. When detected, the vanadium concentration in drinking water is usually 1–6 μg/L with a range of up to 20–100 μg/L.[17,29] The vanadium concentration in fresh surface water depends on geographical difference in leachates and effluents from natural and anthropogenic sources. Typically, surface water contains vanadium concentrations of <3 μg/L with a range of up to 70 μg /L.[30] In the US STORET database for 2007–2008, 3,387 of 3,625 surface water samples contained detectable vanadium concentrations ranging from 0.04 (LOD)–104 μg/L.[31] Concentrations may range up to 220 μg V/L in freshwater in rivers in the Colorado Plateau, where vanadium exists in naturally occurring uranium ores.[27] Some water with high mineral content may contain concentrations up to 10 μg V/L in conjunction with other elements (e.g., fluorides, arsenic). Groundwater sampling in California indicates that the primary vanadium sources in groundwater are leachates of V-rich rocks (mafic and andesitic) in volcanic areas, particularly under aerobic and alkaline conditions; anthropogenic sources contribute substantially smaller amounts of vanadium to groundwater.[32]

Diet

Even though most foods contain low vanadium concentrations (<1 ng/g),[33] food is the major source of vanadium exposure for the general population; the form of vanadium in foods is primarily inorganic tetravalent (vanadyl) and pentavalent (vanadate) compounds including vanadium pentoxide, sodium metavanadate, ammonium metavanadate, sodium orthovanadate, and vanadyl sulfate. The daily requirement for vanadium is probably small (<10 μg) with the highest vanadium sources in black pepper, dill seed, wild mushrooms (0.05–2 μg/g), ground parsley (1.8 μg/g), shellfish (e.g., oysters), freeze-dried spinach (0.5–0.8 μg/g), and some prepared foods.[34] The estimated daily dietary intake for the US population is ~10–60 μg V.[35] In the National Human Exposure Assessment Survey (NHEXAS) study of Midwestern US diets, the estimated daily vanadium dietary intake was 0.34 μg/kg body weight,[36] whereas the estimated daily vanadium intake for adults living near a hazardous waste incinerator with elevated vanadium concentrations in the soil was ~29 μg.[37] The estimated mean daily V intake based on analyses of market basket representatives of the Northern Italian diet was 12.2 μg with a range of 3.3–17.9 μg.[38] Cereals and tubers accounted for 37% of the daily intake compared with 23% for fruits and vegetables. The estimated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

intake for meats, fish, and eggs was 18%, whereas beverages accounted for 15% of the intake. The latter was the highest percentage of the daily intake of all trace elements except boron.

In general, seafood contains higher concentrations of vanadium compared with terrestrial animal food sources. Beverages, fresh fruit and vegetables, cereals, liver, fats, and oil contain smaller amounts (<1–10 ng V/g). The processing of food tends to raise vanadium concentrations.[39] The mushroom, *Amanita muscaria*, contains about 100 times the vanadium concentration (100 ppm) found in other plants and mushrooms.[40] Following the major oil contamination of the marine environment during the Gulf War, the mean vanadium content of edible seafood ranged from ~0.48–1.48 μg/g dry weight.[41] In a study of six fish species in the Adriatic Sea, samples of anchovies contained up to 90 μg V/kg (ppb) fresh weight compared with 79 μg/kg (ppb) fresh weight for red mullet and 45 μg/kg (ppb) fresh weight for mackerel.[42] Sole, angler, and hake had substantially lower vanadium concentrations (<4 μg/kg fresh weight). Wines may contain vanadium. In a study of 68 samples of California and French red wines, the V concentration ranged from 7–90 μg/L with somewhat smaller V concentrations in white wine samples.[43] Vanadium is not listed on the US Food and Drug Administration GRAS (Generally Recognized as Safe) list for addition to food.

Drinking water is a relatively small source of vanadium for the general population with typical vanadium concentrations of <1 μg/L in drinking water; drinking water provides an estimated ~2 μg of the daily vanadium intake in adults.[17,36] In the National Human Exposure Assessment Survey (NHEXAS) of several personal, environmental, and biological media in the upper Midwest United States, the mean vanadium concentrations in standing (4 hours) and flushed (3 minutes running) tap water samples were 1.0 μg/L and 1.2 μg/L, respectively.[36]

Lifestyle

High vanadium concentrations exist in tobacco; typically, smoke from tobacco contains 1–8 ppm V.[33] In a Japanese study, the mean vanadium content in cigarettes was 1.11 ± 0.35 μg/g (ppm); the mean vanadium concentration in mainstream smoke was 0.33 ± 0.06 μg/g.[44] Vanadium is a contaminant of some human albumin solutions in concentrations up to ~600–700 μg/L.[45] Health supplements contain vanadium, particularly those for patients with diabetes. Typical daily intakes of elemental vanadium in the following salts from these supplements are 30–150 mg vanadyl sulfate (9–47 mg V) and 125 mg for sodium metavanadate (52 mg V); however, there are currently inadequate clinical data to determine the efficacy of vanadium supplements for the treatment of diabetes.[46]

ENVIRONMENTAL FATE

The global recycling of vanadium involves the release of vanadium from natural and anthropogenic sources to the air, water, and soil; the transport of vanadium particles in water and air include: wet and dry deposition; absorption; and complexing.[16]

Air

Vanadium enters the air as an aerosol of simple or complex vanadium oxides from anthropogenic sources and as mineral particles of less-soluble trivalent forms from natural sources. Vanadium residence time in the atmosphere is inversely related to particle size. The particle size of vanadium is typically smaller from oil-fueled power plants than from natural sources; thus, the residence time in the atmosphere of discharges from power plants is probably longer than from natural sources. In a Turkish study of urban dust samples, vanadium deposition rates ranged from 20.5–84.9 μg/cm^2/day with an arithmetic mean deposition rate of 45.3 μg/cm^2/day.[47] The authors considered vanadium concentrations in dust as a measure of air pollution from residual oil and coal combustion (i.e., depending on vanadium content).

Soil

Compared with other metals, vanadium is moderately mobile in neutral and alkaline soils, but the mobility of vanadium in acidic soil is relatively low. The weathering of rock may release vanadium into air or water and also precipitate vanadium with polyvalent cations or organic complexing agents. In addition to adsorption to particulate matter, vanadium typically exists in solution in fresh water as the tetravalent vanadyl ion (VO^{2+}, $VO(OH)^{+}$) in reducing conditions or the pentavalent vanadate ion ($H_2VO_4^-$, HVO_4^-) in oxidizing conditions.[48] Both vanadate and vanadyl species adsorb or complex well on mineral or biogenic surfaces.

Water

Relatively small amounts of vanadium are transported via water compared with the sedimentation process. In fresh water, vanadium exists as the vanadyl ion (VO^{2+}, $VO[OH]^{+}$) in reducing environments, whereas pentavalent vanadate (acidic solution, VO^{+}; alkaline

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

solution, VO_4^{3-}) dominates under oxidizing conditions. Transport of vanadium in water occurs primarily in suspension and to a much lesser extent in solution. In water, trivalent and tetravalent vanadium rapidly oxidize to the pentavalent form of vanadium. Consequently, most of the vanadium in fresh water enters seawater adsorbed to colloids or in suspended form. Removal of vanadium dissolved in seawater results from precipitation as hydrated ferric trioxide or by biochemical processes in organic matter. In general, marine plants and invertebrates accumulate much higher vanadium concentrations than terrestrial plants and animals, with bioconcentration more common among lower terrestrial plant phyla than higher, seed-producing phyla, depending on water-soluble vanadium concentrations in the soil, pH, and growing conditions.[16] Although data are limited, human studies do not suggest biomagnification of vanadium in the food chain.[49]

DOSE EFFECT

The toxicity of vanadium compounds depends on a variety of factors including the route of administration and the inherent toxicity of the particular compound. In general, the toxicity of vanadium compounds is low; vanadium toxicity is least following ingestion and greatest following parenteral administration. Inhalation is a route of exposure that produces intermediate toxicity. The toxicity of vanadium increases with higher valences; the pentavalent compounds are usually the most toxic. Acidification tends to reduce the toxicity of vanadium compounds.[50]

Ingestion

Human

Historically, vanadium compounds (e.g., sodium metavanadate) were administered for the treatment of anemia, tuberculosis, diabetes, and syphilis in doses of 1–8 mg sodium metavanadate.[17] Vanadyl sulfate ($VOSO_4$) is a common supplement used to improve performance in weight-training athletes at doses up to 60 mg/day. A 12-week, double-blind, placebo-controlled clinical trial involving 31 weight training athletes did not detect any hematological abnormalities at doses of 0.5 mg $VOSO_4$/kg/day;[51] however, there was no evidence that the use of vanadium improved endurance or physical performance. Loose stool, abdominal cramps, and occasional nausea are common complaints associated with the ingestion of therapeutic doses of vanadyl sulfate.[52] The daily administration of 100 mg $VOSO_4$ for 4 weeks[53] and 125 mg sodium vanadate for 2 weeks[54] to noninsulin-dependent diabetic patients was well tolerated, except for some mild gastrointestinal complaints. The daily ingestion of ammonium vanadyl tartrate of 50–100 mg as a cholesterol-lowering agent for up to ~10 weeks was associated with abdominal cramps, loose stool in all six volunteers; some of the subjects complained of fatigue, lethargy, and a blue-green tongue.[55] Daily doses of 125 mg diammonium vanadotartrate for 5 months produce gastrointestinal side effects in a few subjects,[56] whereas no overt evidence of toxicity occurred in five medical students receiving up to 125 mg diammonium oxytartratovanadate for 6 weeks.[57]

The estimated ingestion of 10–15 g ammonium metavanadate was associated with the development of gastrointestinal symptoms, green tongue, and *focal* neurological lesions (right-sided facial paresis, hemiparesthesia).[58] MRI revealed a high-intensity signal lesion in the left parietal cortex with slight edema in the adjacent subcortical white matter. All clinical symptoms were resolved within 10 days.

Animal

In a study in mice, the toxicity of vanadium trioxide was six times less than vanadium pentoxide.[59] The exposure of rats to 34–155 mg vanadyl sulfate/kg/day in drinking water was not associated with any significant changes in hematocrit, hemoglobin, leukocyte count, or platelet count.[60]

Inhalation

Vanadium pentoxide (V_2O_5) is a potential respiratory irritant. An 8-hour exposure of 1 mg V_2O_5/m^3 to two healthy volunteers produced a cough for 8 days, but no alteration in the pulmonary function tests or chest X-ray; exposure of two volunteers to 0.1 mg V_2O_5/m^3 produced mucous and slight cough that increased 2 days after exposure and resolved within 4 days.[61] Exposure of 24 workers to V_2O_5 at an average concentration of 0.3 mg/m^3 (range up to 5 mg/m^3) was associated with a productive cough, irritation of the nose, throat, and eyes, rhinitis, and green tongue that cleared within several days of cessation of exposure.[62] Low-dose exposure to vanadium causes an increase in nasal inflammatory cells on nasal smears accompanied by symptoms of nasal irritation.[63] Exposure to respirable vanadium dust concentrations of 0.1–139 μg/m^3 was associated with increased adjusted polymorphonuclear cell counts from nasal lavage in nonsmokers but not in smokers.[64] However, large interindividual variations in the polymorphonuclear cell counts occurred, and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. no dose-response effect was demonstrated. Prolonged exposure to high concentrations of vanadium dust in the range of 5–150 mg V/m^3 causes atrophic rhinitis and a persistent inflammation of the bronchi.[17]

Parenteral

Patients with syphilis tolerated doses ranging up to 600 mg V_2O_5 over 13–23 days. Based on clinical experience in the early 1900s, single intravenous doses of 10 mg V_2O_5 were considered safe with renal "irritation" and anorexia being the limiting adverse effects. The administration of 20 mg as sodium tetravanadate was associated with lacrimation, hypotension, throat constriction, vomiting, and apnea.[65]

TOXICOKINETICS

Absorption

The absorption of vanadium compounds depends on their solubility and the route of entry. Inhalation of dusts and fumes is the major route of vanadium exposure for workers. Although the rates of absorption are not well defined, soluble vanadium compounds including V_2O_5 are well absorbed following instillation into the lungs. In contrast, therapeutic doses of vanadium salts (e.g., ammonium vanadyl tartrate) are poorly absorbed that from the gastrointestinal tract;[55] animal studies suggest the amount of vanadium absorbed by the gastrointestinal tract is <1–2%.[66] Dietary vanadium exists either as vanadyl or vanadate, with the latter being absorbed ~3 times more effectively by the gastrointestinal tract than the former; thus, conversion of vanadate to vanadyl in the acid milieu of the stomach contributes to the low vanadium absorption in animal studies.[67] Vanadium remains in the vanadyl form in the alkaline medium of the duodenum. The skin probably is a minor route of exposure as a result of the low lipid/water solubility of elemental vanadium.[16]

Distribution

Following transport in plasma, the distribution of vanadium from the blood is rapid ($t_{1/2}$ ~1 hour) with the highest vanadium concentrations initially appearing in kidney, liver, and lungs. Transferrin reversibly binds vanadyl and vanadate in blood at two metal-binding sites; however, the binding of vanadium to transferrin is most likely in the vanadyl form because this complex is more stable than the vanadate complex.[68] Therefore, ~90% of the vanadium in the blood resides in the plasma, primarily as vanadyl bound to transferrin and albumin.[69] *In vitro* studies suggest that vanadium circulates as a polyvanadate (i.e., isopolyanions containing pentavalent vanadium) in the blood, whereas these studies suggest NADPH-dependent reduction of polyvanadate may form tetravalent vanadyl cations in the tissues (microsomes).[70]

Following the IV administration of 47.6 μg vanadium to five healthy adults, the volume of distribution at steady state was ~54 L.[71] In animal studies, the vanadium concentration in the brain is ~5% of the vanadium concentration in the blood.[72] The total amount of vanadium in the human body is small with the total body vanadium burden averaging ~100 μg.[33] Based on animal studies, the bones and teeth retain the highest vanadium concentrations; these tissues provide a major sink for retained vanadium.[9] Vanadium does not accumulate in the brain of animals or humans.

Elimination

Most ingested vanadium is eliminated unabsorbed in the feces. The kidneys are the principal route of vanadium elimination after absorption with minor amounts (i.e., <10%) excreted via the feces. Following occupational exposure to vanadium dust, urine vanadium concentrations increase significantly compared with unexposed control groups.[73] The excretion of vanadium is relatively rapid; animal studies indicate that the kidney excretes ~40–60% of the vanadium dose within 1–3 days of ingestion.[74] The biological half-life of vanadium in the urine is 20–40 hours.[75] Animal studies indicate that vanadium elimination from the body following inhalation of vanadium oxides is biphasic with an initial rapid rate of elimination (10–20 hours) and a longer terminal phase (40–50 days).[76] In a study of five healthy volunteers receiving a single, intravenous vanadium dose of 47.6 μg in a commercial 20% albumin solution, the serum elimination half-life followed a three-compartment model with half-lives of 1.2 hours, 26 hours, and 10 days.[71] The terminal phase accounted for ~80% of the vanadium dose. About 52% of the vanadium dose appeared in the urine within 12 days of administration.

Maternal-Fetal Kinetics

The vanadium concentrations in human breast milk ranged from 0.11–0.69 μg/g (ppm) in a review of sample of lactating women in Nigeria, Zaire, Guatemala, Hungary, the Philippines, and Sweden.[77] The estimated daily vanadium intake for infants in the United States

was as follows: milk-based powder formula, 0.05 μg; soy-based powder formula, 3.5 μg; and hypoallergenic powder formula, 2.8 μg.[78]

HISTSOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The specific biochemical function of vanadium in animals and humans has not been identified. Although vanadium is not unequivocally accepted as an essential trace metal for humans, it is probably an essential trace element.[79] Features favoring essentiality include rapid excretion, ubiquity in the biosphere, homeostatic regulation with accumulation, and the ability to catalyze the chelation of biologically active compounds.[35] The vanadate ion is one of the most potent inhibitors of the Na^+/K^+ ATPase pump. Recent research suggests that vanadium may help regulate the Na^+ pump. The vanadium-containing haloperoxidases (bromoperoxidases, chloroperoxidases, iodoperoxidases) catalyze the two-electron transport of a halide by hydrogen peroxide. Studies from the 1970s suggested vanadium deficiency produced impairment of reproduction, skeletal abnormalities, and biochemical changes (plasma cholesterol), but the findings were inconsistent and confounded by the ingestion of unbalanced diets. Later studies using balanced diets also demonstrated some biochemical abnormalities (hepatic glycogen and lipids, bone copper, fecal bile acids, plasma cortisol and glucose, thyroid peroxidase activity) in vanadium-deficient guinea pigs.[80,81]

In biological systems, vanadium complexes act as catalases, peroxidases, and nitrogenases involved in a variety of cellular processes including redox processes. There are at least the following three known types of vanadium-containing proteins: vanadium haloperoxidase, vanadium nitrogenase, and the vanadium transport proteins (vanabins).[82] In its lower life forms, vanadium reacts with hydrogen peroxide to form a pervanadate that catalyzes the oxidation of halide ion and stimulates the phosphorylation of receptor proteins.[34] Thyroid peroxidase is the most recognized haloperoxidase in animals. These findings in lower life forms along with recent animal data suggest vanadium is an essential trace element in higher animals including humans.[67]

In vitro and animal studies indicate that vanadate and other vanadium compounds increase glucose transport activity and improve glucose metabolism.[79,83] The action of vanadium is probably distal to the receptor, perhaps related to the translocation of glucose through the plasma membrane. Inhibition of phosphotyrosine phosphatase and protein tyrosine kinase activation is probably involved in the action of vanadium on glucose homeostasis.[84] The enhancement of glucose uptake, glucolysis, and glycogen synthesis by vanadate is less than that of insulin; however, vanadate produces greater simulation of lactate and glucose oxidation than insulin.[85] Both vanadyl and vanadate compounds mimic the action of insulin in isolated cell systems, and these compounds produce dramatic decreases in blood glucose levels in animal models of both types of diabetes mellitus.[86] Additionally, the administration of vanadyl sulfate to streptozotocin-diabetic Wister rats provides some protection against the destructive action of streptozocin on the pancreatic β-cells.[87] Relatively large doses (100 mg vanadyl sulfate/kg/day) are necessary to lower plasma glucose in animal studies.[88] Some laboratories reported toxic effects (e.g., decreased weight gain and renal function, increased mortality) in Sprague–Dawley rats following administration of vanadium doses in the range of 25–75 mg/kg/day.[89] Other laboratories did not detect significant toxic effects of vanadium at doses (i.e., >100 mg/kg/day) that reduced plasma glucose levels in diabetic Wister rats.[90] Peroxovanadium compounds are the most potent inhibitors of insulin receptor tyrosine kinase described to date.[91]

In addition to the insulin-mimetic effects of vanadium compounds, vanadium affects signal transduction mechanisms and proto-oncogene expression *in vitro*.[92] At concentrations of >5 μM, orthovanadate is cytotoxic to proliferating cells, including primary culture and tumor cell lines.[93] These studies suggest that orthovanadate may possess antineoplastic properties.

Mechanism of Toxicity

The systemic effects of vanadium probably result from its oxidizing ability.[63] This metal also inhibits oxidative phosphorylation,[94] but the role of this mechanism in toxicity is unclear. Vanadium acts as a phosphate analog that interferes with a variety of phosphate-containing enzymes including phosphatases, phosphate-transfer enzymes, protein kinases, ribonucleases, phosphatases, and ATPases. Vanadate interferes with phosphate-containing enzymes (ATP phosphohydrolases, adenylate kinase, glyceraldehyde-3-phosphate dehydrogenase, ribonuclease) at relatively high (μmol–mmol) extracellular concentrations.[95] Based on *in vitro* data, vanadate probably is a noncompetitive inhibitor of Na^+/K^+ATPase (K_1 = 880 nM). This vanadium species is a more effective inhibitor of ATPases in concentrations of >50 μM, whereas vanadyl is an effective inhibitor in very low concentrations (10 nM).[96]

Pathological Changes

Human

Postmortem examination of a 24-year-old woman dying after the ingestion of ammonium vanadate demonstrated pulmonary congestion, erosive gastritis, and greenish discoloration of the oral mucosa.[97]

Animal

Acute sodium vanadate poisoning in rats causes acute desquamative enteritis, mild congestion of the liver with fatty changes, and slight parenchymal degeneration of the renal convoluted tubules.[98] High V concentrations over a short duration (e.g., <1 hour at doses up to 0.693 mg V_2O_5/L) produce conjunctivitis, acute laryngotracheitis, bronchopneumonic changes in the lung, and fatty degeneration of the liver.[99] Following acute exposure to 5 mg V_2O_5/m^3, airflow limitation developed in the central and peripheral airways of monkeys without detectable changes in the parenchymal function. Significant increases in the total cell counts were recovered during bronchoalveolar lavage of the lung suggesting a role for pulmonary inflammation in the development of the decrease in flow.[100] In mice administered high doses (i.e., 20 mg V/kg) as ammonium metavanadate, severe necrosis of lymphoid tissue occurred along with pulmonary hemorrhage and acute renal tubular necrosis.[101] The mitochondria probably are an important target of vanadium toxicity. *In vivo* and *in vitro* data suggest that pentavalent vanadium-induced liver toxicity results from disruption of mitochondrial respiratory complexes I, II, and III and subsequent reactive oxygen species and ATP depletion in liver cells.[102] The outcome is cell death signaling via MPT pore opening and cytochrome c release. The oral administration of ammonium metavanadate (AMV) with a maximum dose of 20 mg V/kg/day to male C57BL/6N mice for 7 weeks resulted in marked lipid accumulation in hepatocytes, renal epithelial cells, and mucosal epithelial cells of the small and large intestines along with severe degeneration, necrosis, and loss of mucosal epithelial cells in the small intestine.[103]

CLINICAL RESPONSE

Acute Toxicity

Most clinical effects of vanadium compounds result from local irritant effects on the eyes, upper respiratory tract, and gastrointestinal tract rather than systemic toxicity. Ammonium vanadate is a corrosive that may cause erosive gastritis following ingestion.[58] A 24-year-old woman developed nausea, vomiting, diarrhea, abdominal pain, hypoglycemia, and renal failure after ingesting ammonium vanadate; she died the day after admission from acute respiratory failure.[97]

Environmental Exposure

The International Programme on Chemical Safety (IPCS) reviewed epidemiology studies on environmental vanadium exposure in 1988; they concluded that the data did not support a causal relationship between environmental V exposure and adverse effects.[17] Several studies have suggested environmental vanadium exposure is associated with impaired immunity,[104] cardiovascular morbidity/mortality,[105] and bipolar disorder;[106] however, the lack of adequate control of confounding factors (e.g., other metals, particulates) prevents the establishment of a causal relationship.

Occupational Exposure

Most clinically significant vanadium exposures occur when workers inhale vanadium pentoxide fumes. Exposure to vanadium dust is a well-documented cause of upper respiratory tract irritation characterized by rhinitis, wheezing, nasal hemorrhage, conjunctivitis, cough, sore throat, and chest pain.[3] These symptoms are prominent in boilermakers exposed to high concentrations of V_2O_5 fumes during the cleaning of the boilers with rhinitis and cough particularly prominent; hence the name "boilermakers" bronchitis.[107] Symptoms may be delayed a few days; recovery usually occurs within 2–5 days. Following more severe exposure, an acute bronchitis with dyspnea and expiratory wheezes may develop along with gastrointestinal symptoms and fatigue. Chronic effects are not consistently reported after exposure to vanadium, in part, because of the lack of persistence of vanadium in the lung.[16] Bronchitis and pneumonitis may occur after prolonged exposure, but chronic respiratory dysfunction is not usually associated with occupational V exposure.[108,109,110]

Case series indicate that asthma may develop after heavy exposure to vanadium compounds in vanadium refineries[111] and vanadium mines (mean spot urine vanadium concentration = 52.7 μg/g creatinine; $n = 12$);[112] however, cohort studies have not detected an increased prevalence of asthma to date. A prospective study of boilermakers measured the pulmonary function of 26 male boilermakers exposed for 4 weeks to a complex mixture of gases, vapors, and particles from the combustion of fuel oil. This exposure involved low vanadium concentrations (mean = 12.2 ± 9.1 μg/m^3).

The study demonstrated a significant ($P < 0.01$) mean decrease in the FEV_1 of 140 ± 160 mL; however, there was no dose-response relationship between the vanadium concentration and the change in FEV_1 adjusted for age and smoking.[113] Similarly, there was no correlation between the vanadium concentration and airway responsiveness as measured by methacholine challenge.

Vanadium is a weak sensitizing agent for skin at high concentrations. A study associated the development of dry eczematous dermatitis in 9 of 36 workers who were exposed to vanadium concentrations averaging 6.5 mg V/m^3; only one worker had a positive patch test using 2% sodium vanadate.[1] A green discoloration of the tongue and a metallic taste suggest vanadium exposure. This discoloration usually resolves within a week of the cessation of V exposure depending on the absorbed dose of vanadium.[114] Although workers who were exposed to vanadium compounds have reported nonspecific symptoms (e.g., headache, palpations, weakness, tinnitus, and dizziness), neurological symptoms are not well documented in the medical literature. A Chinese study of steel workers with high (time–weighted average = 0.216 mg/m^3) and low (TWA = 0.013 mg/m^3) vanadium exposure reported some differences in mean scores on the WHO neurobehavioral core test battery between the two groups including error dot score, digit span, digit symbol, Benton visual retention, and correct/error pursuit aiming (but not total pursuit aiming).[115] Limitations of the study include a lack of baseline scores, lack of adjustment for smoking, alcohol, job types, and differences between groups in the Profile of Moods scores (e.g., statistically significant increased scores on anger-hostility, depression-dejection, fatigue-inertia, and vigor-activity in the highly exposed group), and confounding exposures (e.g., manganese, dusts, ammonia).

Reproductive Abnormalities

Although there are few data on reproductive abnormalities in humans, the lack of accumulation of vanadium in reproductive organs suggests vanadium does not cause reproductive abnormalities following exposure to vanadium concentrations that do not produce maternal toxicity. Gavage of male and female rats with sodium metavanadate before mating and during gestation and lactation did not produce any effects on fertility, reproduction, or parturition.[116] Animal studies indicate maternal toxicity occurs before the appearance of teratogenic effects. The no-observed-effect level (NOEL) for maternal toxicity and developmental toxicity for sodium orthovanadate were 7.5 mg/kg/day and 15 mg/kg/day, respectively, following administration at doses of 7.5 mg/kg/day, 15 mg/kg/day, and 30 mg/kg/day to mice via gavage on gestational days 6–15.[117] Both fetotoxicity (reduced fetal weight) and teratogenicity (increased incidence of cleft palate) occurred in Swiss mice following the intraperitoneal injection of sodium metavanadate ($NaVO_3$) at 2 mg/kg/day, 4 mg/kg/day, and 8 mg/kg/day during organogenesis.[118] Abnormalities in sperm count and sperm morphology as well as reduced fertility were detected in CD-1 male mice given 8.5 µg V_2O_5 /g body weight every 3 days for 20 treatments (i.e., 60 days).[119]

Carcinogenicity

The IARC lists vanadium pentoxide as a group 2B (possible) human carcinogen based on an increased incidence of bronchioloalveolar neoplasm in male/female mice and male rats, even though issues were raised regarding improperly characterized exposure data in the test group.[120] The US Toxicology Program does not list vanadium or vanadium compounds as suspected carcinogens. There is inadequate evidence for the carcinogenicity of vanadium or vanadium compounds in humans.

Vanadium is not clastogenic and is weakly mutagenic.[121] No data currently indicate vanadium is definitely carcinogenic, but the possibility of carcinogenicity remains because vanadium interferes with mitosis and chromosome distribution. *In vitro* studies indicate that vanadium pentoxide is not cytotoxic; however, this compound produces rapidly repairable DNA damage (single-strand breaks).[122] Although vanadium compounds have not been thoroughly tested for carcinogenic potential, some animal studies designed to test other toxicological endpoints did not demonstrate an excess incidence of tumors.[123,124] In a 2-year study of F344/N rats and $B6C3F_1$ mice exposed to vanadium pentoxide concentrations ranging from 0.5–4 mg/m^3, there was evidence of carcinogenicity in male and female mice.[125] This exposure caused more pronounced neoplastic response in mice than in rats. There was some evidence of carcinogenicity in male rats based on the incidence of alveolar/bronchiolar neoplasms, but the relationship between alveolar/bronchiolar neoplasms in female rats was equivocal. This exposure caused a wide range of nonneoplastic proliferative lesions in the lungs of rats and mice over the course of the study. *In vitro* studies suggest that some vanadium compounds (e.g., vanadocene dichloride, peroxovanadates with or without a heteroligand) possess some antitumor properties.[126]

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 0.01963 μmol/L
1 μmol/L = 50.94 μg/L

Analytical Methods

Atomic spectroscopic techniques for the determination of vanadium in biological and environmental samples include atomic absorption spectrometry (AAS) with flame and graphite tube atomizers, X-ray fluorescence spectroscopy (XRF), inductively coupled plasma/optical emission spectrometry (ICP/OES), and inductively coupled plasma/mass spectrometry (ICP/MS). Neutron activation analysis (NAA) is a highly sensitive method for the detection of vanadium in biological samples with detection limits in the low- to sub-ppb range. Even though NAA is highly sensitive, disadvantages include high cost and limited availability. Atomic absorption spectrometry is inadequate for measuring vanadium in biological specimens, but electrothermal atomic absorption spectrometry is sufficiently sensitive to detect vanadium at concentrations present in the serum and urine of the general population.[127,128] The range of graphite furnace atomic absorption spectrometry (GFAAS) extends from 10–500 μg V/L at a sample volume of 20 μL. Usually biological and environmental samples are prepared by acid digestion with nitric acid to extract vanadium from the sample matrix. GFAAS and flameless atomic absorption spectrometry (FAAS) are sufficiently reliable and sensitive methods to detect vanadium at ppb in water and wastewater samples. Analytical techniques (liquid chromatography or capillary electrophoresis coupled with electrothermal atomic absorption spectrometry, inductively coupled plasma/atomic emission spectrometry, or inductively coupled plasma/mass spectrometry) are available for the speciation of vanadium into tetravalent and pentavalent forms.[129] The potential redistribution of vanadium species during analysis and the small concentration of this element in samples require separation/preconcentration techniques prior to direct determination.[127] Inductively coupled plasma/atomic emission spectrometry and direct current plasma/atomic emission spectrometry are sensitive methods for the detection of vanadium in air. Contamination-free sampling and sample handling, particularly preconcentration steps, are important quality control procedures.[130] The complexity of the matrices of biological and environmental samples requires techniques to reduce interference with analysis of vanadium concentrations; the main methods for matrix removal are liquid–liquid extraction and solid-phase extraction.[16]

Biomarkers

Before the middle 1970s, wide variation occurred in the measurement of vanadium concentrations in the urine and blood, particularly with the use of colorimetry. The concentrations obtained in these studies probably are too high for comparison with concentrations obtained in more recent studies.[131]

Blood

Limited data on the distribution of vanadium in blood suggest that the vanadium concentrations in plasma/serum and whole blood are similar.[132]

General Population

There is substantial variation in reported blood vanadium concentrations in the general population, probably as a result of variation in analytical techniques. Generally, the whole blood vanadium concentration in the general population without excessive vanadium exposure is <1 μg/L. After a literature survey, Sabbioni et al. estimated the normal value of whole blood and serum vanadium concentration in the general population as ~0.05 μg/L with a range of 0.022–0.937 μg/L depending on sampling techniques, population sampled, and association with environmentally polluted areas.[130] In a study of 52 randomly selected Taiwanese college students, the mean vanadium concentration in whole blood samples was 0.42 μg/L with a range of 0.01–1.20 μg/L. The mean vanadium concentration in the five smokers in this study was 0.47 ± 0.32 μg/L.[133] The median whole blood vanadium concentration in 11 urban adults without occupational exposure to vanadium was 0.056 μg/L with a range of 0.032–0.095 μg/L.[104] The mean V concentration in a study of 130 German residents without occupational V exposure was 0.052 μg/L with a range of 0.016–0.11 μg/L as measured by ICP/MS.[134] In a study of 99 healthy French children, the upper 95% of vanadium in whole blood was 0.35 μg/L compared with 0.41 μg/L in plasma as measured by ICP/MS.[135]

In a convenience sample of 74 Belgian volunteers, the mean serum V concentration was 0.031 ± 0.010 μg/L (range, 0.16–0.94 μg/L) as measured by neutron activation analysis in the 1970s.[132] Serum vanadium concentrations increase above these reference values in patients with renal failure, probably as a result

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of the transfer of vanadium from the purified dialysate water to the blood. In a study of 43 chronic hemodialysis patients, the mean serum vanadium concentration was ~24 ± 11 μg/L related to high vanadium concentrations in tap water (mean $V_{tap\ water}$ = 16.9 μg/L) as measured by a modified electrothermal atomic absorption technique.[136] No adverse effects were attributed to the serum vanadium concentrations. The mean vanadium concentration in 80 chronic dialysis patients was 18.4 ± 7.6 μg/L spectrometry before dialysis as measured by flameless atomic absorption spectrophotometry.[137] After the use of purified water in the dialysate, the postdialysis vanadium concentration decreased to 13.0 ± 5.3 μg/L.

Medical Use

Vanadium is a minor constituent of titanium–aluminum–vanadium alloy used in cementless hip prostheses. Whole blood and serum V concentrations in patients with these hip prostheses are typically higher than in the general population with higher values in symptomatic patients with damaged prostheses than in asymptomatic patients.[138] In a cross-sectional study of 129 consecutive patients attending routine follow-up after implantation of cementless total hip prostheses with titanium-alloy containing acetabular and femoral components, the mean whole blood V concentration in asymptomatic patients was 0.16 ± 0.35 μg/L compared with 0.77 ± 1.40 μg/L in symptomatic patients.[139] The mean duration of the implants was 4.9 years (range, 0.08–28.1 years). The serum V concentrations were slightly higher than the whole blood V concentrations. The mean serum V concentration in asymptomatic patients was 0.18 ± 0.49 μg/L compared with 1.21 ± 2.37 μg/L in symptomatic patients. The difference was not statistically significant as a group. A sensorimotor axonal neuropathy and bilateral sensorineural hearing loss developed in a patient with a broken ceramic-on-ceramic bearing couple and stem containing titanium alloy.[140] The whole blood V and serum V concentrations were 6.1 μg/L and 5.8 μg/L, respectively; the serum Al concentration was 11.5 μg/L. Two months after replacement of the damaged implant, the neuropathy resolved, whereas the sensorineural hearing loss remained unchanged.

Toxicity

A 24-year-old woman developed acute respiratory distress, renal failure, and cardiac arrest within 1 day of ingesting an unknown amount of ammonium vanadate; analysis of inferior vena caval blood detected a blood vanadium concentration of 6.22 mg/L as measured by inductively coupled/plasma mass spectrometry.[97] Initial reports suggested that blood vanadium concentrations decrease during recovery from manic-depressive illness;[141,142] however, subsequent reports have not confirmed a correlation between blood vanadium concentrations and various types of depression.[143,144] A 69-year-old man with a ruptured ceramic-on-ceramic prosthesis (titanium–aluminum–vanadium femoral component) developed a grayish-green tongue, a fistula secreting abundant grayish-black exudate, hypoacousia, and sensorimotor deficits in the lower extremities.[145] Prior to revision, the whole blood and serum vanadium concentrations were 6.1 μg/L and 5.8 μg/L, respectively. Three months after revision, the symptoms resolved except for the hearing loss. At that time, the whole blood and serum V concentrations were 2.6 μg/L and 1.9 μg/L, respectively. The mean serum V concentration in 21 patients with loose total hip prostheses containing femoral stems composed of titanium-aluminum-vanadium alloy was 1.30 μg/L (range, <0.81–1.60 μg/L) compared with <0.81 μg/L (i.e., <LOD) in 21 controls (no implants) and 1.74 μg/L (range, <0.81–2.58 μg/L) in 12 patients with similar, normal-functioning prostheses.[146] The analytical method was graphite furnace Zeeman atomic absorption spectrometry.

Urine

In the general population with typical vanadium exposure, the urine V concentration is usually <1 μg/g creatinine and <8 μg/24-hour urine volume.[147] After a literature survey, Sabbioni et al. estimated the normal value of urinary vanadium concentration in the general population as ~0.5 μg/L with a range of 0.212–0.800 μg/L.[130] In a study of 382 healthy Italians, the mean urine V concentrations were 0.8 ± 0.08 μg/L with a range of 0.05–1.44 μg/L.[148]

Abnormalities

Following exposure to V_2O_5, reductions in forced vital capacity and forced mid-expiratory flow rates may occur within 24 hours. Even following acute, high-dose vanadium exposure, symptoms and signs of respiratory irritation, including reductions of airflow on pulmonary function tests, return to normal within 2–4 weeks.[107,149] Hypoglycemia may complicate severe vanadium intoxication.[97] Serum electrolytes, creatinine, and urea were normal in workers chronically exposed to airborne vanadium concentrations of 0.01–0.5 mg/m^3, suggesting a lack of clinical evidence of renal dysfunction.[63]

HEALTH SURVEILLANCE

Risk Assessment

ATSDR derived an acute-duration inhalation minimal risk level (MRL) for vanadium of 0.8 μg/m^3 based on a LOAEL of 0.56 mg vanadium/m^3 for lung inflammation in rats exposed to vanadium pentoxide 6 hours/day, 5 days/week for 13 days and dividing the human equivalent LOAEL concentration (0.073 mg vanadium/m^3) by an uncertainty factor of 90 (3 for use of a minimal LOAEL, 3 for animal to human extrapolation with dosimetric adjustments, and 10 for human variability).[16] The chronic-duration inhalation MRL for vanadium is 0.1 μg/m^3 based on a $BMCL_{10}$ (lowest lower bound on the benchmark concentration, 40 μg/m^3) for degeneration of epiglottic respiratory epithelium in rats exposed to vanadium pentoxide 6 hours/day, 5 days/week for 2 years. The minimal risk level (MRL) for intermediate-duration oral vanadium exposure of 10 μg/kg/day was based on a NOAEL for hematological and blood pressure effects in humans exposed to vanadyl sulfate for 12 weeks. The US EPA calculated a reference dose (RfD) of 7 μg/kg/day that was without appreciable risk of adverse effects over a lifetime based on gastrointestinal cramping and diarrhea observed in human studies.[150] The no observable adverse effect level (NOAEL) for reproductive toxicity (i.e., based on decreases in sperm count) in male mice administered sodium metavanadate for 64 days prior to mating with untreated females was 0.2 mg sodium metavanadate/mL drinking water.[151]

Environmental Monitoring

Vanadium concentrations near metallurgical industries usually average about 1 μg/m^3, whereas ambient air near industries producing vanadium metal or V compounds contains V concentrations of a few μg/m^3.[17] Very high V concentrations result from boiler-cleaning operations as a result of the high concentration (i.e., ~10–25%) of vanadium oxides in the dust. During these cleaning operations, concentrations of 50–100 mg V/m^3 are frequent, ranging up to 500 mg V/m^3. During an overhaul, 18 boilermakers worked both inside and outside the boiler; the time-weighted average exposures for the boilermakers before and during the overhaul were 1.20 μg/m^3 compared with 8.9 μg/m^3 during the overhaul work.[152]

The US OSHA PEL–Ceiling for respirable vanadium dust and fume, of vanadium pentoxide (V_2O_5), is 500 μg/m^3 and 100 μg/m^3, respectively. The ACGIH recommends an 8-hour TLV–TWA of 0.05 mg/m^3 inhalable particulate matter measured as vanadium to protect workers from airway inflammation after exposure to vanadium pentoxide. In a study of 18 boilermakers, the workers were exposed to median vanadium exposure before and during boiler work of 1.0 μg/m^3 and 12.7 μg/m^3, respectively, during a short-term partial-shutdown.[153] No significant change in any lung function parameter on spirometry occurred when comparing values before, during, and 2 weeks after exposure ceased. Table 34.3 outlines the regulations and guidelines for vanadium concentrations in food, water, and air. The lungs are the primary target organ of vanadium toxicity; therefore, preplacement and periodic medical examinations should carefully document the status of the pulmonary system including chest X-rays and pulmonary function tests. The reporting of upper respiratory tract symptoms is probably the most sensitive indicator of excessive V exposure; however, this sign is not specific to vanadium. Although vanadium is on the US EPA Drinking Water Contaminant Candidate List, it is currently not regulated by existing US national primary drinking water regulations.

Biological Monitoring

URINE

After adjusting for creatinine concentrations, urine vanadium concentrations are probably a more reliable measure of exposure for biological monitoring than blood vanadium concentrations.[154] Samples should be collected several days after pulmonary exposure begins because of the slow diffusion of vanadium through the lungs. The presence of vanadium in the urine documents exposure, but studies of workers exposed to vanadium do not demonstrate a close correlation between ambient air vanadium and urine V concentrations.[16] Marked reduction of urine vanadium levels occurs within 24 hours after cessation of exposure; however, elevated urine vanadium concentrations may persist up to 2 weeks following heavy, acute V exposure.[155] Patients with titanium alloy implants typically have urine V concentrations several-fold higher than reference values, particularly in symptomatic patients.[139] In a study of workers involved in the manufacture of vanadium pentoxide from slag rich in vanadium, the vanadium concentration in urine samples ranged from 3.0–769 μg/L compared with 0.066–53.4 μg/L in controls.[156] The estimated airborne exposure to vanadium was 0.016–4.8 mg/m^3 over a mean of 9.2 years.

TABLE 34.3. Regulations and recommendations for exposure to vanadium and selected vandium compounds.

Description	Value
OSHA	
PEL-Ceiling (transitional)	
Vanadium pentoxide	
(respirable dust)	0.5 mg/m^3
(fume)	0.1 mg/m^3
ACGIH	
TLV–TWA (8-hour)	
Vanadium pentoxide (dust/fume)	0.05 mg/m^3
Ferrovanadium (dust)	1.0 mg/m^3
BEI (end of shift at end of workweek)	
Urine	50 µg/g Creatinine
NIOSH	
REL (15-minute ceiling)	
Vanadium compounds	0.05 mg/m^3
REL-TWA (10-hour)	
Elemental V and vanadium carbide	1 mg/m^3
IDLH	
Vanadium pentoxide (dust/fume)	35 mg/m^3
WHO	
TWA (24-hour)	
Air quality guideline	1 µg/m^3
US EPA	
RfD	
Vanadium pentoxide (oral RfD)	9 µg/kg/day
ATSDR	
MRL	
Acute-duration inhalation	0.8 µg/m^3
Chronic-duration inhalation	0.1 µg/m^3

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; BEI = biological exposure indices; IDLH = immediately dangerous to life and health; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfD = reference dose; TLV = threshold limit value; TWA = time-weighted average; US EPA = US Environmental Protection Agency; WHO = World Health Organization.

The ACGIH currently does not have a biological threshold limit for vanadium;[157] tentative recommended biological exposure limits include 50 µg V/g creatinine for a postshift urine sample with the provision that more data are necessary to validate this value.[158] In individuals without occupational vanadium exposure, the background urine vanadium concentration in morning specimens is usually low (<0.4–0.5 µg/L) as measured by electrothermal atomic absorption spectrometry.[159] The correlation between 8-hour TWA V concentrations and morning urinary vanadium concentrations in this study was poor. In a study of 20 workers exposed to low (0.36–32 µg V/m^3) air concentrations of vanadium during the overhaul of an oil-fired boiler, the urine vanadium concentrations ranged from 190–4,300 µg/g creatinine with a mean V concentration in end-of-week samples of 1,530 ± 530 µg/g creatinine.[160] The median V concentration was 1,520 µg/g creatinine. The study demonstrated that the correlation between the start-of-shift urine vanadium and airborne V exposure on the previous day was stronger than the correlation between the end-of-shift urine vanadium and V exposure on the same day.

Blood

The serum vanadium concentrations in workers exposed to vanadium typically exceed reference values in the general population by up to several orders of magnitude; however, clinical manifestations of illness are unusual other than respiratory tract irritation.[147] A study of 11 ferroalloy plant workers exposed primarily to ferrovanadium dust and V_2O_5 (slag dust) below 1 mg V/m^3 demonstrated a mean whole blood vanadium concentration of 1.82 µg/L (35.7 nmol/L) with 95% CI: 1.52–2.19 µg/L (29.8–43.0 nmol/L) as measured by neutron activation analysis; the mean vanadium concentration was 0.78 ± 0.09 µg/L (15.4 ± 1.8 nmol/L) in six unexposed controls.[154] In an occupational study of vanadium pentoxide production workers exposed to ambient air concentrations of vanadium ranging from 0.016–4.8 mg/m^3, the vanadium concentration in whole blood samples from workers and controls ranged between 3.11–217 µg/L and 0.032–0.095 µg/L, respectively.[132] The average vanadium concentration in whole blood from a convenience sample of volunteers with occupational exposure to vanadium was 33.2 µg/L with a range of 3.10–217 µg/L.[133]

TREATMENT

Treatment is supportive. Usually measures to enhance vanadium elimination from the body are unnecessary because of the lack of persistence of vanadium in the body and because of the dearth of well-documented cases of chronic vanadium toxicity. Little clinical data are available on methods to enhance vanadium elimination. Ascorbic acid was a recommended agent for the treatment of acute vanadium toxicity based on its ability to reduce the pentavalent vanadate ion to the less toxic tetravalent vanadyl ion.[161,162]

Animal studies suggest ascorbic acid is the most effective agent to **prevent** vanadium poisoning; however, deferoxamine and Tiron (4,5-dihydroxy-1,3-benzenedisulfonic acid) were more effective chelating agents following vanadium intoxication in mice compared with Na_2Ca-ethylenediaminetetraacetate (EDTA) and Na_3Ca-diethylenetriaminepentaacetate (DPTA).[163] Based on pharmacological endpoints for these chelators, only deferoxamine reduced vanadium in tissue when administered 8 hours after the injection of sodium metavanadate.[164] The administration of ascorbic acid was associated with increased vanadium in the tissue and no increase in urinary vanadium excretion. Because vanadate is 90% protein-bound, hemodialysis probably would not significantly increase the clearance of this compound.[12]

Chapter 35

ZINC

HISTORY

The use of zinc alloys dates back to the Babylonians over 5,000 years ago.[1,2] Industrial and ornamental applications of zinc included its use in Semitic bronze (23% Zn) and brass. By the late 1800s, an acute febrile reaction (chills, fever, myalgias, headache, nausea, vomiting) was recognized as an illness in brass workers inhaling zinc oxide fumes. This clinical entity has been given various names including spelter chill, zinc fever, brass founders' ague, smelter shakes, and metal fume fever.[3] References to the medicinal uses of zinc appeared in the Ebers' papyrus, written in ~1,500 BC. In this document, the topical use of zinc as calamine was recommended as a therapy to heal lesions around the eye;[4] zinc remains a popular constituent of topical skin and eye preparations. During the late 1700s and early 1800s in Western Europe, zinc oxide and zinc sulfate were treatments for convulsions, gleet (urethral discharge), and vaginal exudates; however, variability of chemical composition and lack of efficacy soon limited the use of these zinc compounds.

Zinc is an essential cofactor for enzymes that control many cell processes including DNA synthesis, normal growth, brain development, behavioral response, reproduction, fetal development, membrane stability, bone formation, and wound healing. Zinc deficiency produces growth retardation, anorexia, delayed sexual maturation, iron-deficiency anemia, and alterations of taste.[5,6] Zinc possesses less toxicity compared with other metals (e.g., lead, arsenic, cadmium, antimony) that contaminate zinc ores;[7] however, fatalities occurred after the accidental infusion of zinc[8] and inhalation of zinc chloride fumes in closed spaces.[9] Today, zinc oxide is the most common cause of metal fume fever.

PHYSIOCHEMICAL PROPERTIES

Zinc is a relatively soft, bluish-white heavy metal that belongs to Group 12 (Group IIB) of the periodic table. This divalent metal reacts readily with inorganic (oxides, phosphates, sulfates) and organic compounds; consequently, elemental zinc and organometallic zinc compounds do not occur naturally in the environment.[10] Although zinc is stable in dry air, the presence of moisture quickly results in the formation of zinc oxide or basic carbonate on the surface of the metal. This metal is frequently alloyed with other metals (copper, aluminum, titanium, magnesium) as a result of the poor strength of metallic zinc. Table 35.1 lists the identifying information and physical properties of zinc and zinc compounds.

Zinc is amphoteric (i.e., dissolves in strong alkalis and mineral acids to form hydrogen and soluble zinc salts). These amphoteric properties (i.e., ability to react as an acid or a base) produce a variety of nonconducting, nonmagnetic zinc salts excluding zinc chromate. Zinc is most soluble in weakly acidic solutions; therefore, the ingestion of acidic foods from vessels composed of galvanized iron may produce adverse gastrointestinal effects. Zinc chloride is an irritating, hygroscopic corrosive salt that forms hydrochloric acid and zinc oxychloride on contact with moist mucous membranes. The fumes of this zinc salt are white with an acrid odor. The pH of some concentrated solutions of zinc chloride in

soldering flux may be 2–3. The taste threshold of zinc in water is ~15 ppm Zn; a definite metallic taste develops at 40 ppm. Opacification of water begins when the zinc concentration in water exceeds 30 ppm. Water-soluble zinc salts include chloride, chlorate, nitrate, and sulfate, whereas carbonate, oxide, phosphate, silicate, sulfide, and organic complexes of zinc are relatively water-insoluble.

EXPOSURE

Production Processes

Elemental zinc occurs rarely in nature.[12] Most zinc production results from the processing of zinc sulfide (ZnS) ores including sphalerite, wurtzite, and marmatite; the more accurate chemical formula for these ores is (Zn, Fe)S because iron frequently replaces zinc

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in these sulfide ores.[10] Initially, the zinc in the ore is concentrated by crushing and grinding, followed by gravity or magnetic methods of separation or flotation and caustic-leaching to prevent loss of zinc during the concentration process. For ores that do not undergo caustic leaching, the production of metallic zinc results from electrolytic processing or smelting in the presence of zinc oxide, heat, coal, and sulfuric acid. Exposure of workers to zinc occurs during smelting, welding, galvanizing, or brass foundry operations. Heating zinc near its boiling point of 908°C in an oxidizing atmosphere produces fresh zinc oxide particles in the respirable range. The inhalation of large doses of zinc oxide causes metal fume fever. During the hot galvanizing process, workers may be exposed to concentrations of hydrochloric acid in ambient air sufficient to cause dental erosions.[13]

Uses

Zinc is the fourth most widely used metal after iron, aluminum, and copper.[10] Metallic zinc commonly provides a protective coating for other metals (e.g., iron, steel) using a variety of processes including zinc plating, zinc spraying, hot-dip galvanizing, electro-galvanizing, or continuous-line galvanizing; zinc is also a constituent of dye casting and alloys.[14] The majority of commercially produced zinc is consumed during the galvanizing of iron and steel or the manufacturing of brass. Zinc improves the structural durability of iron and steel alloys. In contrast to other US coins, US pennies have contained 97.6% zinc and 2.4% copper since 1982. Nickels are 25% copper and 75% nickel, whereas dimes, quarters, and half-dollars have a copper core with a surrounding nickel coating. The ability of the zinc ion to precipitate proteins increases the value of zinc as a component of antiperspirants, styptics, astringents, and mild antiseptics.

Zinc oxide is the most commonly used zinc compound, primarily as a vulcanization activator and accelerator that reduces rubber aging by neutralizing sulfur and organic acids formed by oxidation.[12] Zinc is a solubilizing agent in many drugs (e.g., insulin) and a constituent of dental cement for dentures.[15] Some manufacturers of zinc-containing denture adhesives withdrew these products because of concern that ingestion of large amounts of these adhesives could cause zinc-induced hypocupremia and possibly bone marrow suppression or neuropathies.[16] A causal link was not well-established; zinc-containing denture adhesives remain on the US market. Table 35.2 lists the common uses of various zinc compounds.

Zinc Chloride

Uses include soldering flux, dry battery cells, oil refining, dental cement, and taxidermy. Exposed workers include military personnel, rubber workers, textile finishers, embalmers, and dental cement makers. Zinc chloride is the primary ingredient in smoke bombs used to disperse crowds. During manufacturing processes, irritating substances (i.e., hydrochloric acid, zinc oxychloride) form in the airways of workers following the inhalation of zinc chloride.

Zinc Oxide Nanoparticles

Zinc oxide is a semiconductor with commercial applications in pharmaceutical and solar cell manufacturing, rubber formulation, vulcanizing, and white pigment/ceramic production. Workers exposed to zinc oxide

TABLE 35.2. Uses of zinc compounds. (Adapted from Knapp et al.).[17]

Compound	Uses
Zinc acetate	Wood preservative, mordant, glazes, reagent
Zinc carbonate	Pigment, feed additive, manufacture of porcelains, pottery, rubber
Zinc chloride	Deodorant, disinfectant, antiseptic, wood preservative, fireproofing, soldering flux, cement, batteries, smoke bombs
Zinc chromate(VI) hydroxide	Pigment in paint, oil, varnish, linoleum, rubber
Zinc gluconate	Suggested treatment for common cold
Zinc oxide	Pigments, dental cements, glass tires, glue, matches, white ink, reagent, photocopy paper, flame retardant, fungicide, catalyst in organic synthesis
Zinc phosphide	Rodenticide
Zinc stearate	Tablet and rubber manufacture, cosmetic and pharmaceutical powders, ointments
Zinc sulfate	Mordant, wood preservative, fertilizers, sprays, animal feed additive, rayon manufacturing, starting material for other zinc compounds, textile dying, phosphor in watches/TV screens, pigment

during the heating of zinc-containing alloys include galvanizers, electroplaters, and welders. Zinc oxide nanoparticles have useful commercial uses involving antimicrobial, UV filtering, catalytic, and photochemical properties.[18] Zinc oxide absorbs UV light, particularly the UVA portion, whereas visible light is reflected and scattered.[19] Many sunscreens and cosmetics use nanoparticles of zinc oxide and titanium dioxide to reduce the white, chalky appearance of the older dermal preparations; these nanoparticles easily aggregate (i.e., 20 nm → 130 nm) to reduce the penetration of UV light between gaps in the UV absorption spectrum of normal-sized (i.e., 20 nm) ZnO nanoparticles.[20] Additionally, makeup, shampoo, toothpaste, and anti-wrinkle cream contain nanoparticles to reduce the weight and greasy feeling of these products. Zinc oxide nanoparticles typically do not penetrate the stratum corneum (horny) layer of the intact epidermis. ZnO nanoparticles are often coated with polymers (e.g., aluminum hydroxide, silica oxides) to reduce potential toxicity (e.g., reactive oxygen species) from other routes of exposure.[21]

Zinc Gluconate

Double-blinded, placebo-controlled studies suggest oral zinc lozenges shorten the duration of the common cold in healthy people when administered within 24 hours of the onset of symptoms;[22] however, the use of zinc does not reduce severity. Additionally, the use of zinc lozenges is associated with a high prevalence of adverse effects (e.g., nausea, bad taste).[23] The high degree of heterogeneity of the data indicates the need for cautious interpretation of these data. At concentrations of 0.1 mmol/L, zinc inhibited the *in vitro* replication of several viruses associated with the common cold by preventing the formation of viral capsid proteins and limiting intracellular adhesion.[24] The zinc ion blocks intracellular adhesion molecule 1 in the nasal epithelium, where the human rhinoviruses attach.[25] Evidence to support the use of zinc lozenges in the treatment of children is limited. Of eight double-blind, placebo-controlled clinical trials published before 2000, half the trials found zinc lozenges effective and half found no difference between placebo and zinc.[26] In some studies of children and adolescents with the common cold, the use of zinc lozenges was associated with an increased incidence of minor adverse effects (e.g., diarrhea, throat discomfort, bad taste, nausea) when compared with controls.[27] There is insufficient evidence to recommend the use of zinc supplements for the treatment or prevention of Alzheimer's disease.[28]

Zinc Sulfate

The World Health Organization and UNICEF recommend zinc supplementation during acute diarrheal illnesses in children from developing countries where zinc deficiency is common. Zinc sulfate was the most common zinc supplement given to children in Uttar Pradesh, India, with diarrheal illnesses; the use of zinc gluconate was less common.[29] Although there is insufficient evidence that zinc supplementation reduces death or hospitalization during acute diarrheal illnesses, zinc may shorten the duration of the illness. In a Cochrane review of studies in children aged >6 months with acute diarrhea, zinc supplementation reduced the duration of diarrhea by ~10 hours (mean difference = −10.44 hours, 95% CI: −21.13 to 0.25; n = 2,175).[30] There was moderate evidence that zinc supplementation decreased the duration of the illness beyond 6 days (RR = 0.73, 95% CI: 0.61–0.88; n = 3,865).

Sources

Zinc is a common constituent of the earth's crust. Typical background zinc concentrations in the environment include the following: fresh water, <0.1–50 μg/L; seawater, 0.002–0.1 μg/L; soil, 10–300 mg/kg dry weight; sediments, <100 mg/kg dry weight; and ambient air, <300 ng/m^3.[10] Risk assessment suggests there is no clear evidence that environmental zinc exposure causes adverse health effects.[31]

Air

Zinc release into the air is greater from anthropogenic sources than from natural sources. These anthropogenic sources include metallurgic industries (lead smelting, brass works), zinc-containing fertilizers and pesticides, mining, refuse incineration, coal and fuel combustion, corrosion of galvanized structures, and smelter operations.[32] Mildly irritating zinc ammonium sulfate is a zinc salt emitted during the combustion of fossil fuels.[33] The average zinc concentration in ambient air in the United States is usually <1 μg/m^3 with the arithmetic mean varying from 0.02–0.16 μg Zn/m^3 in urban areas.[12] In the early 1990s, the median zinc concentration in air samples collected across Minnesota was 0.012 μg/m^3 with a maximum of 0.187 μg/m^3.[34] In remote areas, the zinc concentration in ambient air is much lower (i.e., <0.003–0.027 μg/m^3), particularly in winter.[35] Average annual zinc concentration in the air near a smelter was ~5 μg/m^3 with a daily range up to 15.7 μg/m^3.[32] Inhalation of zinc from ambient air is a minor route of zinc exposure for the general population.

Soil

The zinc concentration in cultivated US soils ranges from <5–400 mg/kg (mean = ~36 mg/kg) compared with <10–2,000 mg/kg (~51 mg/kg) in uncultivated soils;[12] however, natural zinc concentrations in the soil can vary by three to four orders of magnitude depending on the presence of zinc-containing ores and types/concentrations of zinc salts used in local commercial activities[10] Releases of zinc to the soil account for the major amount of zinc released from natural and anthropogenic sources to the environment. The major industrial zinc sources include mine tailing, coal and bottom fly ash, and discharges of waste. Zinc concentrations in soil from a reclaimed waste dump of phosphate ore mines averaged ~450–1,100 mg/kg; zinc concentrations were higher in vegetation grown on this land compared with control plots.[36]

Water

Erosion of soil particles containing natural trace amounts of zinc accounts for the major source of zinc in water. Concentrated releases of zinc into water usually result from discharges associated with zinc smelting and refining operations or cadmium and lead operations. Zinc concentrations in surface water are usually <50 μg/L; however, the zinc concentrations may range up to 50 mg/L near concentrated sources (e.g., mines).[37] In freshwater, zinc occurs in the following forms: zinc oxy ions, hydrated ions in complexes of organic matter (humic acid, fulvic acid), and adsorbed to solid particulate matter. Zinc concentrations are higher in sediment compared with water because zinc is transported in an adsorbed or precipitated state. The Zn concentration ranged from 1–2.9 g/kg in sediment from Hamilton Harbor compared with 6–48 μg Zn/L in the surrounding water.[38] In ultrafiltered samples from residential ground water collected in acid-washed Teflon tubing from eastern Long Island, New York, ~40% of the dissolved Zn fraction (<0.45 μm) resided in the colloidal fractionate (1 kDa–0.45 μm) with the remainder in the low molecular weight fractionate (<1 kDa).[39] The precipitation of zinc sulfate occurs under anaerobic conditions in the presence of sulfide ions. Zinc bioconcentrates moderately in aquatic organisms primarily in crustaceans and bivalve species rather than fish.[12]

Zinc concentrations in drinking water may exceed surface water concentrations as a result of water treatment and leaching from water lines. During the late 1970s, 77% of 1,577 US surface water samples contained zinc concentrations of 2–1,200 μg/L, whereas 380 drinking water samples contained zinc concentrations of 3–2,000 μg/L.[37] Higher concentrations in drinking waters are a result of water treatment and contamination from plumbing of the water distribution system. The zinc concentration in drinking water may increase in the distribution systems secondary to the leaching of zinc from piping materials, particularly in soft water with a low pH. Typically, zinc concentrations in Seattle drinking water ranged from ~10–100 μg/L with zinc concentrations in water standing in galvanized pipe ranging up to 1,300 μg/L.[40,41] The zinc concentration in drinking water from houses was ~10-fold higher in houses with galvanized plumbing than copper plumbing. Substantial variation in the concentration of trace metals typically occurs in the same water source over time.

Diet

Zinc is a ubiquitous, essential element. In plants, zinc does not bioconcentrate or biomagnify through terrestrial food chains.[12] The average daily zinc intake ranges from ~5–16 mg (~0.1–0.2 mg/kg body weight) with food and water providing the major sources of zinc intake.[10,42] In an urban Italian study, the mean daily intake of zinc was 3.65 mg with meat accounting for the main contribution of zinc.[43] The mean daily Zn intake in a market basket study of Northern Italian foods was 12.0 mg with a range of 7.5–19.8 mg; the contribution of various food groups was similar, except sweet foods.[44] In a study of diets from 250 Mumbai adults (170 vegetarian, 80 nonvegetarian),[45] the mean daily zinc intake was 6.3 mg compared with means ranging from 5.7–7.9 mg for Mumbai children (6–10 years) as measured by differential pulse anodic stripping voltammetry.[46] Typically, a person must consume a diet rich in high-protein sources to meet the recommended daily adult zinc allowance of 11 mg for men and 8 mg for women (12 mg for pregnant women). US federal regulations permit the addition of zinc chloride, zinc oxide, zinc stearate, and zinc sulfate as food additives; thus, these zinc salts have generally recognized as safe (GRAS) status. The bioavailability of zinc is not well defined because of limited information on factors that affect the mammalian uptake of zinc including speciation, composition of food ingested, body stores of zinc and related metals, physiological status, control mechanisms of zinc in the body, and nutrient-dietary interactions. In general, the absorbed dose is substantially less than the administered dose; diet usually accounts for almost all (i.e., >95%) of the total intake of zinc.[10]

Zinc concentrations in fresh edible potions of vegetables range from ~10–150 mg/kg.[10] In general, meat,

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

dairy products, and eggs contain more zinc than plants, with liver being a rich source of zinc. Seafood (oysters, mussels), meat, dairy products, nuts, legumes, and whole grains also contain relatively high Zn concentrations. The average Zn concentration in meats, poultry, and fish is ~25 mg/kg (ppm).[47]

Lifestyle

A Turkish study did not detect a statistically significant difference ($P > 0.05$) in the mean plasma zinc concentrations between 32 smokers (i.e., at least ½ ppd for 1 year) and 26 nonsmokers; the mean plasma zinc concentration in the nonsmokers was 0.87 ± 0.14 µg/L compared with 0.88 ± 0.13 µg/L for the smokers as measured by atomic absorption spectrometry.[48] A Jordanian study of 56 smokers and 17 nonsmokers demonstrated mean whole blood zinc concentrations of 3.21 ± 0.44 mg/L (range, 1.70–6.48 mg/L) and 6.80 ± 0.26 mg/L (range, 5.16–9.00 mg/L), respectively, as measured by inductively coupled/plasma optical emission spectrometry. A majority of the smokers used >1 ppd.[49] Zinc does not equilibrate across the dialysis membrane; the strong affinity of plasma proteins for zinc causes zinc extraction from the dialysate.

ENVIRONMENTAL FATE

Air

Zinc exists in the environment primarily in the divalent state as an oxidized form (ZnO) bound to submicron particulate matter.[12] Zinc particles with small diameters and low densities suspended in the atmosphere may travel long distances from emission sources. Before deposition, zinc-containing particles/aerosols may undergo chemical transformation in the atmosphere to other zinc compounds (e.g., sulfide, ferrous zinc, phosphide, chloride, elemental zinc).[50] Dry and wet deposition removes zinc from the air with deposition to soil and surface waters.

Soil

Sorption is the dominant reaction of zinc in the environment as a result of the inability of zinc to volatilize from soil or water. In the soil, zinc remains adsorbed to soil; leaching is limited except at waste disposal sites. The relative mobility of zinc in soil and water depends on chemical species (solubility) and soil conditions (e.g., salinity, pH, humic acid concentrations, cation exchange capacity, pH, redox potential); under anaerobic conditions, zinc sulfide is the controlling species.[51] Zinc sulfide is insoluble; hence, zinc mobility in anaerobic soil is low. The mobility of zinc in soil increases at low pH under oxidizing conditions and limited cation exchange capacity (i.e., low calcium).[10] Adsorption of zinc to sediment occurs more readily at pH >7 and low salinity. The deposition of zinc in soil produces relatively small concentrations of the soluble and more mobile form (zinc sulfate). Most contaminated soils contain <1% soluble zinc; consequently, zinc remains primarily in immobile forms in these soils.[52]

Water

The balance between suspended (i.e., undissolved) zinc, dissolved zinc, and zinc adsorbed to suspended matter in waters depends on pH, redox potential, total organic carbon, and speciation. In a study of eight rivers polluted by mining operations, <10% of total zinc was sorbed on particles or colloids in acidic Norwegian river water (pH = 3.1 and 5.1) compared with 21% in water from six rivers with neutral pH.[53] As the pH decreases relatively, more zinc dissolves into the water phase. In surface waters, zinc partitions into sediments through sorption onto organic material, clay, and hydroxides (iron, aluminum, manganese). Zinc exists as a divalent form in aqueous solution that exhibits amphoteric properties. In acidic environments, zinc metals and compounds form hydrated divalent zinc cations, whereas zincate anions form in strong bases including the hydroxo-complexe $[Zn(OH)_3]^-$, $[Zn(OH)_4]^{2-}$, and $[Zn(OH)_4(H_2O)_2]^{2-}$.[12] However, the formation of anionic zinc species is unlikely at the pH of most natural waters. Biomethylation of zinc compounds in aquatic ecosystems is also unlikely because of the instability of alkyl zinc compounds in oxygen and water.

Complexing agents (e.g., humic acid) bind zinc in natural waters. The stability of these complexes depends on pH of the water and the chemical reactivity of the complex. The dissociation of the complex contributes to the amount of free zinc ions in solution; as the pH decreases, the dissociation rate increases with ~50% dissociation of the zinc-humic acid complexes at pH 5.5.[54] The mobility of zinc in anaerobic environments and the presence of sulfides are poor because of the precipitation of zinc in its insoluble form (i.e., zinc sulfide).[55] Consequently, severe zinc contamination occurs primarily near sources of zinc release. Because zinc is an essential metal, organisms naturally concentrate it. Many organisms regulate the internal concentration of zinc within certain limits; therefore, zinc tissue concentrations do not necessarily

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

reflect ambient concentrations.[10] Bioaccumulation of zinc occurs to a moderate extent (i.e., ~50–1,000 times), particularly in crustaceans and bivalve animals; zinc does not concentrate in plants above zinc concentrations present in the soil.[56] Consequently, significant biomagnification of zinc in the food chain does not occur.[57,58,59]

DOSE EFFECT

Zinc gluconate tablets contain 14.3% zinc by weight, while zinc sulfate contains 40.5% zinc by weight.

Ingestion

Acute Toxicity

Ingestion of 1–2 g zinc sulfate (405–810 mg elemental Zn) produces emesis.[60] Emesis usually occurs when the concentration of zinc salts in fluid from galvanized zinc containers exceeds 675–2,000 ppm(mg/L). Gastrointestinal irritation (i.e., nausea, vomiting, abdominal pain) developed in 26 of 47 healthy volunteers after ingesting zinc sulfate tablets (2 mg Zn/kg/day) for 6 weeks.[61] The ingestion of 12 g elemental zinc over 2 days by a 16-year-old adolescent was associated with lightheadedness, slight ataxia, lethargy, and headache, but no gastrointestinal complaints occurred.[62] Severe nausea and vomiting occurred within 30 minutes of the ingestion of 4 g zinc gluconate (~570 mg elemental zinc) by a 17-year-old adolescent; he recovered within 7 hours.[63] No diarrhea, gastrointestinal irritation, neurological dysfunction, or hepatic inflammation developed.

Zinc chloride is an extremely soluble zinc salt that possesses corrosive properties. Ingestion of 1 g $ZnCl_2$/kg by a child resulted in minimal systemic effects.[64] Ingestion of 3 oz of solder flux (11% $ZnCl_2$) by a 24-year-old resulted in lethargy, vomiting, pharyngitis, esophagitis, mucous membrane irritation, and mild pancreatitis, but serious systemic effects did not occur.[65] Although the zinc chloride content varies between fluxes, most fluxes contain ~11% $ZnCl_2$. The intentional ingestion of a 35% solution of $ZnCl_2$ produced severe upper pharyngeal corrosion, subcutaneous emphysema of the upper chest, and severe corrosion of the stomach that resulted in gastric obstruction.[66]

Chronic Toxicity

The recommended daily allowance of zinc for adults is 15 mg compared with 3–5 mg Zn in infants. In groups with adequate copper intake, adverse effects do not occur with the daily ingestion of <50 mg zinc.[10] Long-term studies of the ingestion of zinc in humans have not detected signs of gastrointestinal irritation at doses below 4.3 mg/kg/day.[67,68] The daily ingestion of 440–660 mg $ZnSO_4$ for 10 months[69] and 1–2 g elemental Zn over several months[70] produced a copper deficiency (sideroblastic anemia, hypochromic microcytic anemia, neutropenia). The chronic ingestion of >425 pennies was associated with diarrhea, gastrointestinal bleeding, and a fatal bacterial and fungal sepsis.[71] The composition of the pennies was 97.6% Zn and 2.4% Cu. The daily ingestion of 850–1,000 mg zinc gluconate as a dietary supplement was associated with severe anemia and neutropenia that resolved with copper supplementation.[72] Nausea, vomiting, fever, severe anemia, and elevated plasma zinc concentrations were associated with home dialysis with water that contained ~6 mg Zn/L.[73] Following the ingestion of 4.3 mg Zn/kg/day as $ZnSO_4$ for 6 weeks by healthy volunteers, the mitogenic response of peripheral blood lymphocytes and the phagocytic activity of polymorphonuclear leukocytes were impaired, but no abnormalities developed in the number of lymphocytes or T cell and B cell subsets.[67]

Inhalation

Mild reduction in forced expiratory flow rates occurred following a 30-minute exposure to fumes from zinc oxide containing 77 mg Zn/m^3; pulmonary function tests did not demonstrate abnormalities in workers exposed to 8–14 mg Zn/m^3 for up to 8 hours.[74,75] Two volunteers developed symptoms of metal fume fever after exposure to zinc oxide fumes for 5 minutes and 12 minutes, respectively, at an estimated concentration of 600 mg/m^3.[76] In a study of 26 welders exposed to zinc oxide fumes ranging from 70–140 mg/m^3, 2 workers developed clinical features of metal fume fever.[77] Mild increases in body temperature (1.4 ± 0.3°F) occurred in 10 of 13 subjects exposed to zinc oxide concentrations of 5 mg/m^3 for 2 hours.[78] No cases of metal fume fever occurred in a study of 20 zinc foundry workers exposed to zinc oxide fumes at concentrations up to 36.3 mg/m^3 for <4 hours.[79]

TOXICOKINETICS

Absorption

Ingestion

Zinc absorption occurs via passive diffusion and a saturable carrier-mediated process (cysteine-rich intestinal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

protein) throughout the gastrointestinal tract; in rodent studies, the largest portion of zinc absorption occurs in the second part of the duodenum.[80,81] The amount of absorption depends on several factors including the amount of zinc, the type of food consumed (e.g., coingestion of calcium or phosphorus in dairy products decreases zinc absorption),[82] and the zinc requirements of the body. Based on isotope studies, a person with a normal diet absorbs an average of ~20–40% of the zinc present in the diet.[83] The body homeostatically regulates zinc absorption with zinc deficiency by increasing zinc absorption from the gastrointestinal tract; saturable transport mechanisms limit Zn absorption following excessive Zn intake.[84] The presence of trace metals (cadmium, copper, mercury) and phosphates in the diet reduces zinc absorption. Similar to other metals, zinc induces production of the metal-binding protein, metallothionein. This protein binds to zinc in the mucosal cells covering the gastrointestinal tract. By excretion of the metallothionein-zinc complex during the sloughing of these cells, metallothionein helps prevent the absorption of excessive amounts of zinc.[85] In a study of 12 healthy volunteers receiving 20 mg organic zinc (zinc gluconate) or inorganic zinc (zinc oxide) daily for 14 days, the time to maximum concentrations was ~1.5–2 hours with some rebound occurring 16–24 hours after the last dose.[86] The mean maximum Zn concentration at the end of 14 days of Zn gluconate was 1.25 ± 0.18 mg/L, whereas similar amounts of Zn oxide produced slightly lower values.

Inhalation

The amount of zinc absorbed by the lungs is not well defined. Elevated zinc concentrations in workers exposed to zinc oxide fumes suggest the lungs absorb zinc oxide, but some gastrointestinal absorption of particles cleared by the cilia cannot be excluded.[87]

Dermal

Data on the absorption of zinc through the skin are limited. Some absorption of zinc through damaged skin occurs in burn patients treated with zinc oxide dressings.[88]

Distribution

As one of the most abundant trace elements in the body, zinc is present in all human tissues and fluids; however, zinc does not accumulate in the body. The absorbed zinc dose distributes to muscle, bone, liver, pancreas, prostate, and kidney as well as other organs. Muscle and bone contain ~63% and 28%, respectively, of the total body zinc burden based on ^{65}Zn tracer studies in healthy adults.[89] The average amount of zinc in the adult body is ~1.4–2.3 g.[90] The prostate contains relatively high zinc concentrations, probably because of the presence of the zinc-containing enzyme, acid phosphatase. In the plasma, albumin binds ~$^2/_3$ of the zinc with the balance bound mostly to α_2-globulins.[91]

Elimination

Zinc elimination results primarily from fecal excretion (i.e., 70–80%) with relatively little zinc (i.e., 15–25%) appearing in the urine and sweat. Based on the elimination of radioactive zinc administered orally, daily zinc elimination averages ~1% of the absorbed dose in patients with alcoholic liver disease.[92] Fecal excretion of zinc increases as the intake of zinc increases.[93] Following parenteral or oral zinc administration, the biological half-lives range from 100–500 days.[60,89]

Maternal-Fetal Kinetics

Zinc concentrations are typically higher in maternal blood than cord blood. The geometric mean maternal and cord whole blood zinc concentrations in 148 mothers from Mumbai, India, were 6.33 ± 0.12 mg/L and 2.53 ± 0.13 mg/L, respectively, as measured by differential pulse anodic stripping voltammetry; the maternal whole blood/cord blood ratio was ~2.5.[94] A study of 56 mothers living in Singapore demonstrated a mean zinc concentration in maternal blood of 4.97 ± 1.15 mg/L compared with 1.58 ± 0.45 mg/L in cord blood.[95] Stages of lactation affect the zinc concentrations in human milk. In a French study of 82 lactating mothers, the peak zinc concentration (12.0 ± 4 mg/L) occurred 2 days postpartum and declined to 5.0 ± 1.4 mg/L 6 days postpartum as measured by flame/atomic absorption spectrometry.[96] Zinc concentrations in breast milk decline significantly in the months following birth.[97] Although plasma Zn concentrations in 41 lactating Polish mothers increased from the initiation of lactation to the formation of mature milk, the zinc concentration in their breast milk declined.[98] The mean maternal *plasma* zinc concentration increased from 0.51 ± 0.13 mg/L (0–4 days postpartum) to 0.76 ± 0.20 mg/L (10–30 days postpartum), whereas the zinc concentration in their *breast milk* decreased from 8.2 ± 2.8 mg/L to 1.4 ± 0.7 mg/L, respectively. In a study of 25 lactating Libyan women, the mean zinc concentration in their breast milk declined from 16.1 ± 2.7 to 4.95 ± 1.3 mg/L over the first 3 weeks of lactation.[99]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Zinc is a cofactor for >200 biologically important enzymes (e.g., alcohol dehydrogenase, carbonic anhydrase, carboxypeptidase), particularly enzymes involved in protein synthesis.[64] Adverse effects of zinc deficiency in humans include neurosensory changes, respiratory infections, diarrhea, impaired neuropsychological functions, growth retardations, delayed wound healing, immune disorders, dermatitis, and oligospermia. Causes of these deficiencies include poor dietary intake, long-term parenteral nutrition without supplementation, and enteral causes such as malabsorption.[100] Hypogonadal dwarf syndrome has been associated with zinc deficiency characterized by hypogonadism and growth retardation along with anemia, dysosmia, altered taste, poor wound healing, and hepatosplenomegaly. Acrodermatitis enteropathica is an inherited disorder of zinc deficiency manifested by alopecia, hypertrophic and ulcerated skin, chronic diarrhea, and muscle wasting. An abnormally low zinc concentration in breast milk has been associated with the development of zinc deficiency in breast-fed newborns characterized by acrodermatitis, irritability, and delayed growth.[101] Albumin-bound plasma zinc is the metabolically active zinc pool in the body. Zinc in bone is relatively inert, except during periods of calcium mobilization from bone.

Mechanism of Toxicity

Zinc chloride is a caustic agent that causes irritation of the alimentary and respiratory tracts. Excessive zinc intake interferes with copper absorption, probably by the induction of metallothionein; this protein has a higher affinity for copper than zinc. Consequently, more copper is bound to metallothionein and excreted into the feces.[102] Anemia may develop as a result of zinc-induced copper deficiency. Elevated Zn concentrations also reduce serum concentrations of high-density lipoprotein cholesterol while causing a transient elevation in serum low-density lipoprotein cholesterol.[67] Bone marrow aspirates demonstrate cytoplasmic vacuolization of myeloid and erythroid precursor elements; however, a variety of other conditions (e.g., nutritional deficiencies, myeloproliferative syndromes, acute alcohol intoxication, drug reactions, malignant hematological conditions) produce cytoplasmic vacuolizations.[103] High zinc concentrations impair lymphocyte and neutrophil function. Several case reports associate elevated serum zinc, very low serum copper, and low plasma ceruloplasmin concentrations with pancytopenia, myelopathy, and neuropathy; some of these patients improved with cessation of the use of zinc-containing denture pastes.[104,105,106] Publication bias and determination of the initial abnormality (i.e., low serum copper/ceruloplasmin vs. high serum zinc concentrations) limit conclusions regarding causation.

The exact mechanism of action of metal fume fever is unknown; however, an immune response to zinc oxide in the respiratory tract probably produces inflammation and the release of pyrogenic cytokines with zinc as a hapten and a zinc-protein conjugate as the antigen.[78,107] Experimental studies on the inhalation of zinc-coated steel fumes from metal inert gas brazing indicate acute inflammation occurs in humans 24 hours after exposure based on the increase in serum C-reactive protein.[108] *In vitro* experiments indicate zinc oxide exposure causes dose-dependent release of proinflammatory cytokines (e.g., pulmonary tumor necrosis factor-alpha, interleukin-6, interleukin-8) and pulmonary neutrophils.[77,109] In experimental studies of smoking and nonsmoking volunteers, smoking did not increase these inflammatory cytokines; however, there was a dose-dependent relationship between smoking and interleukin-1 when compared with the nonsmoking group.[110] Both divalent zinc and zinc oxide stimulate the formation of free oxygen radials as measured by the luminol-amplified chemiluminescence assay.[111] Exposure to zinc oxide fumes during welding was associated with an increase in pulmonary inflammation as defined by an increase in polymorphonuclear leukocytes recovered in bronchoalveolar lavage fluid.[75] In this study, 4 of 14 welders developed symptoms of metal fume fever. There were no clinically significant changes in airway reactivity or pulmonary function. Experimental studies indicate the development of clinical tolerance to the acute effects of zinc oxide inhalation in workers during recurrent exposure; these changes result in decreased pulmonary inflammation (i.e., reduced alveolar neutrophil and plasma IL-6).[112] The latter substance may act as a pyrogen and an anti-inflammatory agent. In experimental human studies, zinc toxicity was associated with impaired immune and inflammatory responses. Zinc oxide nanoparticles are relatively more toxic than other metallic oxide nanoparticles as a result of oxidative stress, inflammatory, and ion-shedding properties.[113] Although these properties potentially induce specific signaling pathways (e.g., necrosis, apoptosis), the clinical significance of the potential effects remains unclear.

Pathological Changes

Zinc compounds can produce irritation and corrosion of the gastrointestinal tract following ingestion. Acute tubular necrosis and interstitial nephritis may occur. Inhalation of high zinc chloride concentrations and other constituents of smoke bombs in closed spaces produces a chemical pneumonitis and acute respiratory distress syndrome (ARDS). Typically, severe damage to the mucous membranes of the upper respiratory and tracheobronchial tracts manifests by edema, yellow-gray discoloration, and necrosis.[114,115] Two autopsies of workers dying following the detonation of smoke bomb material in a tunnel revealed pulmonary edema and severe inflammation of the mucosa in the upper respiratory tract.[116] Autopsies from patients dying within 20–30 days after inhalation of zinc chloride along with other constituents of these devices demonstrated extensive interstitial and intraalveolar fibrosis with obstruction of the pulmonary arteries and widespread occlusion of small vessels.[117] In these patients, the injury to venous vessels appeared more severe than other types of ARDS, including contracture of preacinar and intraacinar arterial and venous vasculature.[118] Zinc concentrations in all tissues were within the normal range; no zinc particles were present on examination of lung tissue at autopsy.

CLINICAL RESPONSE

Acute Toxicity

The principal adverse effects of excessive oral zinc exposure include nausea, vomiting, abdominal pain, anemia, and occasionally pancreatitis. Following the ingestion of large doses of zinc compounds, vomiting almost universally occurs together with abdominal pain and diarrhea. Hematemesis may develop in severe cases, particularly with corrosive compounds (e.g., zinc chloride). Zinc compounds produce more prominent gastrointestinal symptoms compared with elemental zinc. Lethargy, slight ataxia, and difficulty with writing developed following the acute ingestion of 12 g elemental Zn over 2 days without the appearance of gastrointestinal symptoms.[62] Zinc chloride is a corrosive, particularly in concentrations exceeding 20%; serious ingestions produce partial and full thickness burns of the oral mucosa, pharynx, esophagus, stomach,[17] and laryngotracheal tree[119] with the subsequent development of dense scarring and clinically significant strictures.[120] The corrosive actions of zinc chloride dominate the clinical presentation following ingestion; systemic zinc toxicity is rare in children following the ingestion of zinc chloride.[121] Both animal and human data indicate the liver is not a primary target organ for zinc toxicity.[122,123] Hypotension, diarrhea, vomiting, pulmonary edema, jaundice, hyperamylasemia, oliguria, anemia, and thrombocytopenia occurred after an intentional injection of zinc sulfate.[8]

Environmental Exposure

Most of the severe injuries following exposure to the smoke from the detonation of zinc chloride bombs occur in closed spaces; evaluation of patients following exposure to this smoke in open spaces reveals less severe respiratory symptoms that do not usually cause permanent pulmonary dysfunction.[124] Inhalation of high concentrations of zinc chloride smoke produces a biphasic respiratory syndrome characterized initially by mucous membrane irritation, cough, lacrimation, and dyspnea followed within 24 hours by persistent respiratory symptoms that may persist for several weeks.[125] In severe cases, acute respiratory distress syndrome (ARDS) may develop. During World War II, 10 people died and numerous other patients developed respiratory distress following the detonation of material from a smoke bomb in a tunnel.[116] This episode involved the inhalation of fumes from a smoke bomb in a closed space that produced high concentrations of zinc chloride (i.e., estimated 33,000 mg Zn/m^3) along with other constituents (calcium silicate, hexachloroethane, zinc oxide, an igniter). Most survivors complained of dyspnea, retrosternal chest pain, stridor, rhinitis, and lacrimation. No toxic changes appeared in the kidney or liver. In the survivors of an intense exposure to the smoke from zinc chloride smoke bombs, delayed sequelae included the development of emphysematous blebs[126] and a progressive acute respiratory distress syndrome beginning several weeks after exposure.[117] Greater pulmonary damage typically occurs following exposure to zinc chloride than at similar concentrations of zinc oxide.

Skin lesions are unusual following exposure to elemental zinc and zinc compounds, in spite of the long history of the use of these compounds to treat skin lesions. In an experimental study, no skin irritation developed in volunteers following the application of 25% zinc oxide ointment to the skin for 48 hours.[127] Zinc chloride and zinc acetate are more irritating to the skin than zinc sulfate and zinc oxide.

Similar to acute overdose, the chronic ingestion of excessive amounts of zinc compounds produces a

variety of gastrointestinal symptoms along with hematological effects including copper deficiency, varying degrees of anemia,[128] and neutropenia.[72,129] Current clinical data do not indicate that chronic ingestion of zinc compounds causes increased susceptibility to disease.

Occupational Exposure

Metal Fume Fever

Metal fume fever (brassfounder's ague, metal shakes, zinc fever, zinc chills, Spelter's shakes) is an acute influenza-like illness associated with the inhalation of metallic oxides in the workplace. Typically, metal fume fever is a benign, self-limited illness that resolves within 12–48 hours following cessation of exposure.[130,131] Exposure to high ambient air concentrations of freshly oxidized zinc oxide fumes (i.e., 77–600 mg/m^3) over several hours is the most common cause of metal fume fever;[12] aerosolized zinc oxide powder does not produce similar symptoms.[131] Other causes of this illness include exposure to fumes of aluminum, antimony, copper, iron, magnesium, manganese, and nickel in welding, galvanizing, or smelting operations. The onset of symptoms begins ~4–10 hours following exposure to zinc oxide fumes, typically in the evening after exposure to the fumes. Fatigue, chills, fever, headache, myalgias, cough, dyspnea, leukocytosis, thirst, metallic taste, and salivation characterize this usually mild illness. Resolution of symptoms occurs ~36–48 hours after the onset of illness. Although some patchy infiltrates may occur in more serious cases,[132] the chest X-ray is usually clear. Tolerance develops in workers following recurrent exposure; however, this tolerance may dissipate over the weekend ("Monday Morning Fever"). The reduction in pulmonary function and the radiographic abnormalities usually resolve following cessation of exposure. A cross-sectional study of 11 zinc-coated steel welders, 10 nonwelders with indirect exposure to welding fumes, and 17 controls did not detect a statistically significant difference in airflow on pulmonary function tests between the three groups.[74] The highest exposure to welding fumes was 5.1 and 8.0 mg/m^3 as measured by PAS-6 samplers. A volunteer study of galvanized mild steel welders detected clinically minimal changes in pulmonary function following exposure to zinc fumes; there was no statistically significant correlation between cumulative zinc exposure and pulmonary function.[75] The diagnosis of metal fume fever is primarily clinical with diagnostic testing usually normal in uncomplicated cases.

Hypersensitivity Reactions

Zinc may act as a sensitizer in the occupational setting. Some,[133] but not all,[134] older studies of workers associated zinc oxide exposure with the development of a pruritic, pustular rash; however, the role of personal hygiene and other factors cannot be excluded as causative factors of these rashes. A case report suggests that urticaria and angioedema may develop following exposure to zinc fumes at a zinc-smelting plant.[135] Rare case reports associate the galvanizing of metals in heated zinc with the development of hypersensitivity to zinc and occupational asthma. A galvanized metalworker with chest tightness, dyspnea, and wheezing had a positive immediate reaction to a skin test for zinc sulfate.[136] During workday monitoring, the forced expiratory volume in one second (FEV_1) fell to a maximum of 24% from the baseline at the end of the day; bronchial responsiveness increased the following day. Inhalation challenges with zinc sulfate produced immediate decrease of 23% from the baseline in the FEV_1. There was no documented elevated body temperature to suggest metal fume fever; symptoms requiring intermittent use of an inhaler persisted 3 months after leaving work. A smelter developed recurrent symptoms of bronchiolitis (fever, cough, dyspnea) 3 years after beginning exposure to zinc fumes; the symptoms resolved spontaneously after cessation of exposure. The lack of tolerance, the late emergence of symptoms, and a marked increase of CD8 T cell lymphocytes in bronchoalveolar lavage suggested hypersensitivity pneumonitis.[107]

Reproductive Abnormalities

Zinc is an essential element for normal fetal growth and development; however, there is no clear evidence that zinc supplementation improves pregnancy outcomes in healthy mothers eating well-balanced diets.[137] The weight of the evidence indicates zinc is not genotoxic or teratogenic; however, zinc deficiencies may cause preterm births and increased perinatal mortality.[138] Studies of mothers given zinc supplements (aspartate, citrate, sulfate) during their pregnancy have not demonstrated reproductive abnormalities.[139] Pregnant women receiving capsules containing 0.3 mg zinc/kg/day as zinc sulfate during the last two trimesters did not exhibit any changes in maternal body weight gain, postpartum hemorrhage, or infection.[140] There are few animal or human data to indicate that zinc causes developmental abnormalities at concentrations that do not produce maternal toxicity.[141] A report listed the occurrence of three stillbirths and one premature delivery in a group of women

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

taking 0.6 mg Zn/kg/day as zinc sulfate supplements during the third trimester of pregnancy. The clinical significance of this case report is questionable because the report did not include a comparison to controls or the total number of women observed. A case-control study of women giving birth to children with neural tube defects demonstrated a statistically significant ($P = 0.03$) increase in the zinc concentration of the mothers of children with neural tube defects compared with controls.[142] However, conditional logistic-regression analysis showed the increase in the risk of neural tube defects in women with elevated serum zinc concentrations was not statistically significant. Animal studies suggest exposure to high concentrations of zinc in the range of 100–200 mg/kg/day produces reduced fetal weight, alopecia, anemia, and increased fetal resorption; however, the effects of zinc are difficult to separate from the development of zinc-induced deficiencies of copper and iron.[143] The parenteral administration of single doses of 12.5–25 mg $ZnCl_2$ during days 8–11 of gestation in CF-1 albino mice produced skeletal anomalies without accompanying soft tissue defects.[144]

Carcinogenesis

Neither the IARC nor the US National Toxicology Program lists zinc or zinc compounds as suspected carcinogens. Limited data exist on the incidence of cancer in workers exposed to zinc. No statistically significant relationship between zinc exposure and the occurrence of cancer was demonstrated in a cohort of 4,802 male workers exposed at least 1 year during 1946–1975 to electrolytic zinc and copper refining plants based on death certificates; there was no adjustment for smoking.[145] The overall SMR for the cohort of zinc refinery workers ($n = 978$) was 82. An excess of lung cancer mortality was associated with living near an old lead-zinc mining and smelting area, but the lack of control of confounding variables including carcinogens (smoking, radon, arsenic) limits any conclusions regarding the contribution of zinc to the prevalence of lung cancer.[146]

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 0.0153 μmol/L
1 μmol/L = 65.38 μg/L

Analytical Methods

Atomic absorption spectrometry using a furnace atomizer is the routine technique for determining zinc in biological materials based on sensitivity and cost; however, neutron activation analysis and inductively coupled plasma/atomic emission spectroscopy are more sensitive analytical techniques in blood (NIOSH Method 8005) and urine (NIOSH Method 8310), particularly for multielemental analysis in the sub-ppm range.[12]

Lower limits of detection for graphite furnace atomic absorption spectroscopy, anodic stripping voltammetry, and inductively coupled plasma mass spectrometry are ~6 ng/L in water samples and 10 μg/kg in solid samples.[10]

Sample preparation usually involves acid digestion with concentrated acids. Because zinc is a ubiquitous trace element, inaccuracies may result from the failure to institute proper procedures to prevent the contamination of biological samples with exogenous zinc (e.g., anticoagulants, evacuated tubes, preservatives, rubber stoppers, sampling and filtration equipment, inadequate reagent purity, atmospheric deposition).[147] Some anticoagulants (e.g., citrate, EDTA, oxalate) effectively chelate metallic ions; therefore, the presence of these anticoagulants in collection tubes artificially reduces the plasma zinc concentration.[10] Variability in the concentration of trace metals in rivers reflects the unique chemistry of the river as much as the input of trace metals from anthropogenic sources.

Biomarkers

Blood

Typical whole blood Zn concentrations are 4–7 mg/L compared with 0.6–1.2 mg/L in plasma or serum. Average whole blood concentrations of zinc exceed mean plasma zinc concentrations by a ratio of ~6–8 because of the relatively high zinc content in erythrocytes compared with serum or plasma.[148] In a study of 1,000 Swedish adults in their 70s, the mean whole-blood/serum Zn ratio was 8.56 as measured by inductively coupled plasma/sector field mass spectrometry.[149] The median ratio in this group was similar (8.70) to the mean. The mean whole-blood/plasma Zn ratio in an Italian study of healthy subjects without excessive zinc exposure was 6.87; the mean whole blood Zn concentration was 6.34 mg/L (range, 4.08–7.59 mg/L) compared with 0.92 (range, 0.59–1.21 mg/L) in plasma.[150]

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

General Population

There are no simple measures of the total body Zn burden. Although plasma zinc concentrations are usually low in severe zinc deficiency, plasma zinc concentrations do not necessarily reflect total body zinc burden because the plasma contains relatively small amounts of the total body zinc burden.[151] In healthy adults, the plasma Zn concentration is <1.5 mg/L; lower zinc concentrations (e.g., 0.8 mg/L) occur in elderly patients confined to a hospital.[152] A study of 12,741 French adults revealed a statistically significant (but clinically small) difference in the serum zinc concentrations between women (mean, 0.84 mg/L, 95% CI: 0.60–1.09 mg/L) and men (mean, 0.88 mg/L, 95% CI: 0.63–1.12 mg/L; $P < 0.0001$).[153] In a study of 66 Greek children (mean = 7.53 ± 3.31 years) and their parents, the mean serum zinc concentrations were similar (i.e., ~1 ± 0.2 mg/L) between the two groups.[154] The mean zinc concentration in whole blood from a convenience sample of Spanish medical personnel was 6.95 ± 1.08 mg/L as measured by square wave voltammetry; there were no anthropogenic sources of zinc, and zinc concentrations increased with age.[155] A Spanish study suggests smoking does not significantly alter the serum zinc concentration as measured by inductively coupled plasma/mass spectrometry.[156]

Toxicity

The initial serum zinc concentration in a child after ingesting two mouthfuls of soldering flux containing 22% $ZnCl_2$ was 9.5 mg/L.[17] The patient developed lethargy and frequent episodes of vomiting along with a markedly inflamed gastric antrum. Five hours after the ingestion of 4 g zinc gluconate by a 17-year-old adolescent, the serum Zn concentration was 4.97 mg/L.[63] This patient developed severe nausea and vomiting, but the patient recovered within 7 hours without sequelae. Following the intentional ingestion of ~190 g $ZnCl_2$ by a 20-year-old woman, the plasma Zn concentration 1 hour later was 39.1 mg/L; she was agitated, complaining of retrosternal chest pain.[157] The presence of stridor required 11 days of intubation. Endoscopy revealed ulcerative and necrotic lesions in the gastric fundus. She recovered after a prolonged hospitalization.

Postmortem

In a Polish study of 50 postmortem samples from cases without excessive Zn exposure, the mean blood concentration of zinc (sample site not reported) was 6.81 ± 1.21 mg/L with a median of 7.00 mg/L as measured by flame atomic absorption spectrometry; the range was 4.02–8.68 mg/L.[158] The liver contained the highest mean postmortem zinc concentration with a mean of 39.6 ± 16.1 mg/L (range, 16.0–78.8 mg/L).

Urine

In a study of 683 healthy Italians without occupational zinc exposure, the mean urinary Zn concentration was ~0.45 mg/L (range, 0.27–0.85 mg/L).[150] In a Japanese study of >275 workers at an aluminum alloy fabricating plant without occupational exposure to zinc, the geometric mean zinc concentration in 24-hour urine samples was ~0.5 mg.[159] The urinary zinc concentrations remained consistent over the 13-year study period. There are limited data on the correlation between urinary zinc concentrations and zinc exposure. The amount of zinc in 24-hour urine collections from healthy subjects typically ranges from ~300–600 µg. Various factors (e.g., sickle cell disease, burns, diuretics) increase Zn excretion.[160] Depletion of zinc stores produces a reduction in urinary zinc excretion in *healthy* subjects.[161] Although zinc may interfere with results from urine drug of abuse screens, the urine zinc concentration required to alter these results is extremely high. The addition of zinc to urine samples in concentrations 5,000 times higher than controls produces false-negative results on enzyme multiplied immunoassay technique (EMIT)-based drug abuse testing; self-administration of 200 mg zinc gluconate orally did not alter the results of ELISA-based drug testing.[162]

Abnormalities

Metal Fume Fever

Following the development of zinc oxide-induced, metal fume fever, leukocytosis occurs; pulmonary function tests may demonstrate temporary reductions in lung volumes and carbon monoxide diffusing capacity. These changes along with the increase in bronchiolar leukocytes do not usually produce chronic pulmonary disease.[163] About 20 hours after exposure to zinc oxide fumes at concentrations of 77–153 mg Zn/m^3, bronchoalveolar lavage demonstrated elevated polymorphonuclear leukocytes and lymphocytes (i.e., T helper cells, T suppressor cells, activated killer T cells).[75] The leukocytosis lasts ~12 hours after the fever resolves.[164] Although mild elevations of serum zinc concentrations may occur within 24 hours following exposure to zinc oxide fumes,[165] the zinc concentration in the blood is usually normal during the course of acute metal fume fever.[166] Case reports associate an acute, temporary reduction in expiratory flow rates in workers exposed to zinc oxide fumes during the heating of zinc wires[167] and the soldering of galvanized metal.[168]

Zinc Compounds

Oral

Sideroblastic anemia, myelodysplasia of the bone marrow, copper deficiency, and neutropenia are characteristic of chronic zinc intoxication.[169] Elevated serum glucose, alkaline phosphatase, and amylase concentrations along with depressed serum calcium concentrations may occur in cases of zinc intoxication.[62,65] Following low daily $ZnSO_4$ doses (i.e., 0.5 mg Zn/kg), no alterations of serum glucose, plasma insulin concentrations, or glucose tolerance occur in healthy volunteers.[170] Low plasma copper concentrations frequently occur following the chronic ingestion of excessive amounts of zinc compounds.[171] Routine blood chemistries and physical examinations revealed no hepatorenal disease among 12 workers exposed to zinc oxide fumes for 4–21 years during the production of brass alloys.[87]

Inhalation

Exposure to high concentrations of zinc chloride in confined spaces produces pulmonary edema, pneumonitis, diffuse alveolar damage, and pulmonary fibrosis. Initial abnormalities on high-resolution CT scan of the lungs involve patchy or diffuse ground-glass opacities with or without consolidation.[172] Clinical symptoms do not always correlate to pathological changes on chest radiographs, particularly in the first 48 hours after exposure. Most patients demonstrate a reduction of FEV_1, FVC, total lung capacity, and D_{LCO} with normal FEV_1/FVC ratios consistent with a restrictive impairment. These impairments typically improve, but pulmonary fibrosis may occur. In a case series of 13 soldiers exposed to zinc chloride during a combat exercise, lung diffusion capacity and total lung capacity 4 weeks after exposure declined from baseline values of ~16% and ~4%, respectively; these values returned to baseline 2–6 months postexposure.[173]

HEALTH SURVEILLANCE

Risk Assessment

The estimated safe amount of zinc is 0.15 mg/kg based on a safety factor of 3 in a study demonstrating depression of erythrocyte copper-zinc superoxide dismutase following the ingestion of ~60 mg Zn daily for several weeks.[174] The ATSDR derived a minimal risk level (MRL) of 0.3 mg Zn/kg/day for intermediate oral exposure based on the development of reduced erythrocyte superoxide dismutase activity (a sensitive measure of copper status) and decreased serum ferritin concentrations in women receiving a 10-week course of zinc gluconate (50 mg Zn/day).[175] Dietary studies of women indicate a lowest observable adverse effect concentration (LOAEL) of 1 mg Zn/kg/day with a threshold concentration of 50 mg Zn/day.[176] The US EPA also adopted 0.3 mg/kg/day as an oral reference dose (RfD).

Environmental Monitoring

The US OSHA PEL–TWA for zinc chloride fumes is 1 mg/m^3, whereas the STEL is 2 mg/m^3. These concentrations are designed to reduce the risk of damage to the eyes, respiratory tract, and skin. European countries permit similar zinc chloride exposures. The US OSHA limit for zinc oxide fumes is 5 mg/m^3 (fume or respirable fraction) as a PEL–TWA and 10 mg/m^3 as a STEL to reduce the incidence of metal fume fever. Table 35.3 lists various regulatory and recommended concentrations of zinc in air and water. The maximum contaminant level (MCL) for US drinking water is 5 mg Zn/L.

Biological Monitoring

There are no well-defined biological exposure limits for zinc.[177] Blood and urine zinc concentrations do not correlate well to zinc concentrations in ambient air;[178] limitations of this correlation include the natural diurnal variation in blood and urine zinc concentrations.[179] Zinc concentrations tend to peak during the morning, whereas the nadir occurs in the late evening.[180]

Blood

In a study of 20 Chinese zinc foundry workers, serum zinc concentrations did not correlate to airborne exposure of zinc ranging up to 36.3 mg/m^3 over <4 hours (mean air sample concentration = 3.16 mg/m^3).[79] The serum zinc concentrations for these workers averaged ~0.75 mg/L (11.5 μmol/L) during an 8-hour shift. In an Egyptian study of 61 workers in the galvanization process of an iron and steel manufacturing company, the mean serum zinc concentration was 0.88 ± 0.43 mg/L compared with 0.77 ± 0.14 mg/L in 50 administrative controls ($P < 0.001$) from the same factory.[181] The mean serum copper concentration was significantly lower in workers than in controls. Although the incidence of metal fume fever in the workers was ~25%, there was no significant difference in pulmonary function of chest X-ray abnormalities between the two groups.

TABLE 35.3. Guidelines and regulations for zinc compounds.

Exposure Limit	Value
Air	
OSHA	
PEL–TWA (8-hour)	
Zinc oxide	
(fume)	5 mg Zn/m^3
(total dusts)	15 mg Zn/m^3
(respirable fraction)	5 mg Zn/m^3
Zinc chloride (fume)	1 mg Zn/m^3
Zinc stearate	
(total dust)	15 mg Zn/m^3
(respirable fraction)	5 mg Zn/m^3
ACGIH	
TLV–TWA (8-hour)	
Zinc oxide (fume, dusts)	2 mg Zn/m^3 [a]
Zinc chloride (fume)	1 mg/m^3
Zinc stearate	3 mg Zn/m^3 [a], 10 mg Zn/m^3 [b]
TLV–STEL (15-minute)	
Zinc oxide (fume, dusts)	10 mg Zn/m^3 [a]
Zinc chloride (fume)	2 mg Zn/m^3
NIOSH	
REL–TLV (10-hour)	
Zinc oxide (fume/dust)	5 mg Zn/m^3
Zinc chloride (fume)	1 mg Zn/m^3
Zinc stearate	
(total dust)	10 mg Zn/m^3
(respirable fraction)	5 mg Zn/m^3
REL–STEL (15-minute)	
Zinc oxide	
(dust)	15 mg Zn/m^3
(fume)	10 mg Zn/m^3
Zinc chloride (fume)	2 mg Zn/m^3
IDLH	
Zinc oxide (fume/dust)	500 mg Zn/m^3
Zinc chloride (fume)	50 mg Zn/m^3
Water	
US EPA	
Secondary MCL – public water	5 mg Zn/L
Ambient water quality criterion	5 mg Zn/L
NAS	
Drinking water standard	5 mg Zn/L

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; NAS = National Academy of Sciences; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average; US EPA = US Environmental Protection Agency; US FDA = US Food and Drug Administration.

[a] Respirable particulate matter; [b] Inhalable particulate matter.

URINE

Occupational studies suggest urine is the best medium to monitor exposure to zinc. Urine zinc concentrations probably more closely reflect zinc exposure than plasma or whole blood because homeostatic mechanisms increase urine zinc concentrations following excessive zinc exposure; however, neither sample closely correlates to zinc exposure. In a study of 20 Chinese zinc foundry workers, urinary zinc concentrations correlated with airborne zinc exposure ranging up to 36.3 mg/m^3 over <4 hours (mean air sample concentration = 3.16 mg/m^3).[79] Concentrations of zinc in serum and urine for these workers averaged 11.515 µmol/L (0.75 mg/L) and 3.6705 µmol/L (0.24 mg/L), respectively, during the period of an 8-hour shift. Examination of these workers did not detect evidence of metal fume fever or pulmonary abnormalities. In patients with symptoms of acute zinc chloride poisoning, the urinary zinc concentration may exceed normal concentrations by three times.[182]

TREATMENT

Decontamination

Zinc chloride and zinc acetate are mild-to-moderate corrosive agents; contamination of the eyes or skin with these substances requires immediate irrigation with copious amounts of saline, particularly if the concentration of these substances exceeds 10–25%. The usual measures for gastrointestinal decontamination (ipecac or lavage, charcoal, cathartics) are usually unnecessary, especially if vomiting has occurred or the patient ingested the substance >1 hour before arrival at the medical facility. Case reports suggest that whole-bowel irrigation is an effective adjunct to other decontamination measures for radiopaque tablets (e.g., zinc sulfate) that pass beyond the pylorus.[183] However, there are no clinical studies that confirm the efficacy of whole bowel irrigation.

Chelation

Case reports suggest calcium disodium ethylenediaminetetraacetate ($CaNa_2EDTA$) is potentially an effective zinc chelator based on the successful clinical use of this compound to normalize zinc concentrations.[64,65] Clinical data confirming the efficacy of chelation in humans are very limited. Chelation with $CaNa_2ETDA$ and BAL that began 74 hours after the ingestion of zinc chloride by a 16-month-old toddler was

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

associated with clinical improvement within 24 hours; however, no significant excretion of zinc appeared in the urine.[119]

Animal experiments suggest some polyaminecarboxylic acids (diethylenetriaminepentaacetic acid (DTPA), cyclohexanediaminetetraacetic acid (CDTA)) are more effective chelators of zinc than $CaNa_2$ EDTA;[184,185] however, clinical data to confirm the efficacy of DTPA and of CDTA are lacking. Other potential zinc chelators based on experimental data include *N*-acetylcysteine; in rats, this compound increases urinary zinc excretion.[186] D-penicillamine increased mortality in animal models and probably is not an effective chelator of zinc.[65]

Supplemental Care

Treatment for the ingestion of zinc compounds is primarily supportive with careful attention to fluid and electrolyte balance. Symptomatic patients should be evaluated endoscopically for esophageal and gastric burns if the patient ingested a corrosive zinc salt (chloride, acetate) that exceeded a concentration of 20–25% Zn. H_2 receptor antagonists and/or sucralfate may be helpful for superficial burns of the upper gastrointestinal tract. Treatment of copper deficiency with oral or intravenous copper may be necessary following chronic zinc intoxication. Patients with chronic zinc intoxication should be evaluated for copper deficiency, particularly if anemia and leukopenia are present.

After acute inhalation of corrosive zinc compounds (e.g., zinc chloride-containing smoke bombs), careful attention should be directed to the adequacy of oxygenation as measured by pulse oximeter or arterial/venous blood gases. Support includes artificial ventilation, high-dose steroids, antibiotics, and positive end-expiratory pressure; however, few data exist to guide management with these modalities. Complications include pneumothorax, pneumomediastinum, and acute respiratory distress syndrome (ARDS). Case reports suggest high-dose steroids and venovenous extracorporeal life support may improve survival from ARDS.[187] The treatment of metal fume fever in otherwise healthy workers is supportive (rest, hydration, antipyretics, nonsteroidal anti-inflammatory drugs); patients with cardiopulmonary disease may require stabilization in the hospital. Peppermint oil and milk are ineffective home remedies for metal fume fever.

Chapter 36

ZIRCONIUM

HISTORY

Zirconium was known in Biblical times as the golden gemstone, zircon. The name zirconium is derived from the Arabic word *zargun* for this gem. In the Middle Ages, colorless zircon was considered an inferior diamond. The German chemist, Martin Klaproth, discovered zirconium in 1789 after analyzing the gem. Isolation of zirconium did not occur until the work of the Swedish chemist Jöns Jacob Berzelius in 1824. Commercial production of pure zirconium did not develop until the 20th century as a constituent of ceramic pigments, glass, chemicals, foundry equipment, and metal alloys. In the late 1940s, the corrosion resistance and poor neutron absorption of zirconium lead to the prominent use of this metal inside nuclear reactors and nuclear submarines. In the 1950s and 1960s, several case series associated the use of organic zirconium-containing deodorants (e.g., sodium zirconium lactate, zirconium oxide) with the development of axillary granulomas.[1] The US Food and Drug Administration subsequently banned the use of aerosolized zirconium preparations;[2] however, some deodorants continued to contain lower zirconium concentrations (i.e., <20% Zr anhydrous weight) in combination with aluminum.

PHYSIOCHEMICAL PROPERTIES

Elemental zirconium (Zr, CAS RN: 7440-67-7, atomic mass: 91.22 g/mol) is a bluish-black, amorphous powder or a hard, shiny, grayish-white, heavy metal that is a member of Group 4 (Group IVb) of the periodic table with titanium and hafnium. Because elemental zirconium is highly reactive, zirconium commonly occurs in nature as zirconium dioxide (ZrO_2), zirconium silicate (zircon, $ZrO_2.SiO_2$), or complex zirconates (ZrO_3^{2-}). Zirconium is a passive metal that develops a protective oxide film following exposure to air or water, similar to titanium, chromium, niobium, and tantalum. The most common valence is the tetravalent oxidation state. This metal forms alloys with most metals except mercury including alkali and alkaline earth groups. Zirconium does not form covalent bonds with carbon; therefore, zirconium does not interact well in biological systems or easily form organic compounds. Zirconium exists naturally in five stable isotopes with ^{90}Zr being the most common (51%).[3] There are 28 artificial isotopes (78–110) with ^{93}Zr being a by-product of a fission reaction and the longest lived ($t_{1/2}$ = 1.53×10^6 years). ^{95}Zr is one of the most prevalent fragment products in uranium fission with a half-life of 64 days.

Zirconium possesses high density (SG = 6.5107 at 25 °C), heat resistance (MP = 1,852 ± 2°C), and corrosion resistance along with poor water- and acid-solubility. When mixed in air with oxidizing agents, zirconium powder is flammable. Water-insoluble zirconium compounds include zirconium oxide, zirconium acetate, zirconium hydroxide, and zirconium silicate, whereas zirconyl chloride ($ZrOCl_2$) and zirconium lactate are water-soluble. Zirconium carbide and zirconium oxychloride are slightly water-soluble. Following exposure to water, zirconium tetrachloride decomposes into zirconyl chloride and hydrochloric acid. The physical ability to capture neutrons is a desirable property for the use of zirconium in the nuclear industry.

EXPOSURE

Uses

Elemental zirconium is a component of furnace bricks, high-temperature textiles, optical lens-grinding powders, and metal alloys for nuclear, aerospace, and medical (e.g., orthopedic, dental implants) applications.[4,5] The nuclear industry accounts for most of zirconium production. Additional commercial applications of metallic zirconium include a scavenger in the steel industry, a "gas getter" in vacuum tubes, ceramic colorant, and a constituent of photoflash bulbs. Experimental applications for zirconium phosphate nanoparticles include drug delivery to cancer cells.[6] Zirconium tetrachloride salt is a tanning agent and a textile water repellent, whereas cubic zirconia is a sparkling artificial gem composed of zirconium oxide. Water-soluble zirconium salts were components of cosmetics, deodorants, and topical ointments, but the formation of granulomas following absorption through damaged skin limited their use.[7] In 1977, the US FDA declared zirconium an unsafe constituent of drugs and cosmetics;[2] aluminum zirconium compounds were considered safer antiperspirant components and remained on the market.[8]

Sources

Zirconium compounds are common constituents of minerals throughout the universe including S-type stars, the sun, moon, and the earth's crust (i.e., ~10–300 ppm).[9] Zirconium is substantially more abundant in the soil than copper and zinc. In surface waters, Zr concentrations typically occur in the very low ppb range (e.g., 0.1–20 ppb). Zircon ($ZrO_2 \cdot SiO_2$) and baddeleyite (ZrO_2) are the most abundant commercial zirconium ores. Most commercial production of zirconium occurs as a by-product of titanium ores (rutile, ilmenite). Potential occupational exposures to zirconium include the preparation of zirconium-containing alloys, zirconium casting and refining operations, and the use of zirconium-containing substances (e.g., grinding powder, enamels, porcelain, abrasives). A Japanese study of ambient dose rate and activity concentration of natural radionuclides in raw materials, products, and aerosols including radon in an unshaped refractory, a shaped refractory, and an electrocast refractory plant processing zirconium ores did not detect radiation doses exceeding current workplace standards.[10] The annual maximum effective dose for workers was 0.43 mSv. The typical daily dose of zirconium in the diet is about 4 mg.

ENVIRONMENTAL FATE

Most zirconium compounds are water-insoluble; thus, these compounds do not easily enter living organisms. The low water solubility and the strong affinity of Zr for soil constituents limit soil mobility; however, speciation and physicochemical properties (organic content, pH, texture) of the soil affect Zr mobility.[11] At the pH present in the environment, insoluble hydrous zirconia forms from water-soluble zirconium compounds released by industry. These compounds are deposited in sediment as inert compounds. Zirconium oxide and hydroxide are poorly water-soluble and precipitate at low pH. In general, the translocation of zirconium from soil to plants is low with most Zr accumulating in roots.[11]

TOXICOKINETICS

Most zirconium compounds are water-insoluble with limited absorption. The low oral toxicity of zirconium probably results from poor absorption of zirconium by the gastrointestinal tract.[12] In a ^{95}Zr tracer study of 13 healthy adults followed for 100 days, the total fraction absorption of Zr in citrate-buffered and zirconium oxalate solutions was 0.1% and 0.7%, respectively.[13]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Zirconium is not an essential component of any known biological process. The use of organic zirconium salts (e.g., $NaZrC_3H_5O_3$, sodium zirconium lactate) as a deodorant was associated with the development of dusky, red–brown, discrete papular granulomatous reactions in the axilla.[14,15] These lesions occurred primarily in the central portion of the axillas. In rabbit studies, intradermal and subcutaneous injections of sodium zirconium lactate produced acute inflammatory reactions and granulomas characterized by histiocytes and some giant cells along with macrophages containing a foamy, granular substance.[16] A daily 20-minute exposure of 44% sodium zirconium lactate mist to six albino rabbits for 6 weeks was associated with the development of bronchiolar abscesses, lobar pneumonia, and peribronchial granulomas.[17]

CLINICAL RESPONSE

Environmental Exposure

Subcutaneous granulomas develop from repeated use of deodorant sticks and lotions for poison ivy that contain

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

zirconium lactate and zirconium dioxide,[1,18] probably as a result of hypersensitivity reactions.[19] Although these reactions typically involved sodium zirconium lactate or zirconium oxide, a case report associated the development of an acute hypersensitivity reaction with exposure to aluminum zirconium complex.[20] This 27-year-old woman developed axillary granulomas following the use of aluminum zirconium complex characterized by a caseating necrotic lesion with multinucleated giant cells, lymphocytes, and plasma cells, as well as acute inflammation with abscess formation in the mid dermis and subcutaneous tissues.

Podoconiosis is a noninfectious (nonfilariasis) disease of barefoot workers living in tropical regions of the North African Rift Valley, Central America, and Northwest India with volcanic soils; persistent contact with irritant volcanic soils causes an inflammatory reaction, fibrosis, and obstruction of lymphatic flow.[21] The disease manifests as chronic, bilateral, asymmetric lower limb swelling (i.e., elephantiasis) with pruritus, burning, oozing, mossy papillomata, and rigid toes. Epidemiology studies suggest the volcanic soils in areas with podoconiosis contain higher zirconium and beryllium concentrations than control areas without this disease.[22] The abnormal inflammatory reaction appears to be genetically determined. The etiology of the disease remains unclear; however, the presence of zirconium is a suspected contributing factor to predispose patients to the dermal dehydration and cracking of lower extremity skin necessary to facilitate entry of mineral particles and microorganisms into the lymph.[23] The role of beryllium sensitization and lymphoid granuloma formation also remains unclear.

Occupational Exposure

Minimal toxicity has been associated with the use of zirconium in industry. Rare case reports associate zirconium exposure with pulmonary disease; however, most epidemiological studies do not detect excessive pulmonary disease in zirconium workers. A case report associated the development of a slowly progressive pulmonary fibrosis in a worker who spent 39 years grinding and polishing lenses containing zirconium oxide, aluminum oxide, and silica; confounding exposure to fibrosing silica limits conclusions regarding the causal role of zirconium exposure.[24] Lung biopsy did not detect pulmonary granulomas, and lymphocyte proliferation studies did not document evidence of lymphocyte activation. A 25-year-old with a history of atopic dermatitis worked as sorter and tile glazer for 3½ years; her exposure included clay, quartz, wollastonite, and zirconium silicate with no regular use of protective respiratory devices. She subsequently developed dry cough and dyspnea.[25] Lung biopsy demonstrated granulomatous interstitial pneumonia with mild fibrosis consistent with hypersensitivity pneumonitis. Analysis of pulmonary particles revealed primarily clay minerals and silicates including zirconium silicate. Limited epidemiological studies of zirconium workers have not detected an increased incidence of pulmonary diseases. A study of 22 workers exposed for 1–5 years to fumes from a zirconium-reduction process did not demonstrate any clear relationship between zirconium and pulmonary diseases including pneumoconioses.[26] No significant increase in radiographic abnormalities appeared in a study of 136 workers exposed for an average of ~4 years to dust containing ~10% zircon (zirconium silicate).[27] A study of 32 workers exposed to respirable zirconium dust in the range of 0.67–3.2 mg/m^3 for a mean of ~5 years did not demonstrate pulmonary abnormalities based on questionnaires, pulmonary function tests, and chest x-rays.[28]

Zirconium oxychloride is a potential upper respiratory irritant as a result of the hydrolysis of this water-soluble compound to hydrochloric acid. Animal studies suggest exposure to high zirconium tetrachloride concentrations may produce significant respiratory irritation;[29] however, no human data are available to confirm adverse pulmonary effects in workers inhaling this substance.

Carcinogenesis

Neither the IARC nor the US Toxicology Program recognizes zirconium or zirconium compounds as suspected carcinogens. Little data exist on the carcinogenicity of zirconium in animals; the kinetics of zirconium in the body does not favor the role of zirconium as a carcinogen.

DIAGNOSTIC TESTING

SI Conversion Units

1 μmol/L = 91.22 μg/L
1 μg/L = 0.01096 μmol/L

Analytical Methods

Analytical techniques for quantifying zirconium include atomic absorption spectrometry (LOD, 44 μg/L),[30] inductively coupled plasma/mass spectrometry (LLOQ, 0.7 μg/L),[31] quadrupole/inductively coupled plasma/mass

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

spectrometry (LLOQ, 0.008 μg/L),[32] and inductively coupled plasma/atomic emission spectrometry (LLOQ, 50 μg/L).[33,34] The latter technique lacks the sensitivity of ICP/MS. Using ultrasonic nebulization and a desolvating membrane, the LLOQ for zirconium in serum was ~0.015 μg/mL as measured by ICP/MS.[35] A 13-year follow-up study of 178 workers exposed to zirconium compounds typically of <10 mg/m^3 did not detect any significant abnormalities on chest radiographs or pulmonary function tests.[36] Zirconium oxide is radiopaque.

HEALTH SURVEILLANCE

The US OSHA PEL–TWA for zirconium compounds is 5 mg Zr/m^3 with a STEL of 10 mg Zr/m^3. The American Conference of Governmental and Industrial Hygienists recommends similar values to prevent pulmonary irritation.[29] NIOSH recommends an IDLH value of 500 mg Zr/m^3.

TREATMENT

Treatment is supportive. Because of the low toxicity of these compounds, recommendations for decontamination and treatment should be based on the presence of toxins other than zirconium.

To my grandchildren, Sophia, Henry, Hayden, and Brody
You bring so much joy to our family. I wish you a bright future and the treasured gifts of a loving family, loyal friends, meaningful work, and faith to guide your journey.

Grandpa

To my daughter Abigail, and my wife Karen
Thank you for the things too numerous to list.

Dad/Rob

FOREWORD

The multivolume *Medical Toxicology of Occupational and Environmental Exposures* covering metals, radiation, and cancer is the eagerly awaited third instalment in the seminal series of medical toxicology textbooks written by Dr. Donald Barceloux. The first two books focused on natural substances and drugs of abuse, respectively, and have quickly established themselves as reference works in their respective fields. The comprehensive coverage of topics coupled with a consistent and easy-to-follow organization of content have made them indispensable companions of physicians and researchers alike.

The newest volumes in the series, created by Dr. Barceloux and edited by Dr. Robert Palmer, is a worthy successor to the first two books. Once again, the focus is on naturally occurring and man-made toxic threats that all medical toxicologists will have heard of but few will have had first-hand experience with. This is precisely what makes this work so valuable. The first volume literally comprises an A–Z of all there is to know about the clinical toxicology of metals and metalloids, from aluminum to zirconium. Chapters on well-known toxic metals such as arsenic, lead, and mercury are almost textbooks in their own right covering their subjects in a breadth and depth rarely seen in other publications. But who would know where to look for information on the toxicokinetics of rare earths, or whether tellurium is a human teratogen?

There is an ongoing debate on whether radiation is a subject that toxicologists should concern themselves with, or whether it would best be left to physicists, radiologists, and oncologists. The second volume takes a pragmatic view: if it induces a toxic response, then it is of relevance to anyone involved in the prevention, diagnosis, and treatment of human exposures. Consequently, the chapters in the section on radiation provide a comprehensive summary on what is known about potential health effects of all forms of radiation, and what may be done to prevent them.

The final volume on cancer departs from the familiar substance-based approach of the rest of the book in that it starts from the point of view of the risk assessor, looking at the mechanism of chemical carcinogenesis and then providing an organ-centered overview. This is a useful approach since carcinogenicity is as much governed by the cascade of molecular events elicited by carcinogens as it is by human physiology, biokinetics, and organ response.

In contrast to standard textbooks on clinical toxicology, *Medical Toxicology of Occupational and Environmental Exposures* is not only aimed at those working in the treatment of the poisoned patient. As the most comprehensive source of information in its field, it will equally be an invaluable reference for occupational physicians and hygienists, those working in environmental health and indeed anyone concerned with the human health risk assessment of exposure to metals, radiation, and chemical carcinogens. It is a truly interdisciplinary work that will stand the test of time.

Professor Martin F. Wilks, MD, PhD, ERT, FRCP (Edin), FBTS, FEAPCCT

PREFACE

This volume, *Radiation*, along with *Cancer* and *Metals and Metalloids* in the three-volume *Medical Toxicology of Occupational and Environmental Exposures* is a continuation of the *Medical Toxicology Series* that began with *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals* and *Medical Toxicology of Drug Abuse: Synthesized Chemicals and Psychoactive Plants*. The *Medical Toxicology Series* provides in-depth, evidence-based coverage of the most important human toxins. Similar to the rest of the *Medical Toxicology Series*, the goal of this volume is the creation of a comprehensive and convenient reference that answers questions regarding medical toxicology issues. This volume presents the basic and clinical science associated with the various types of ionizing and nonionizing radiation.

The reader will recognize the similarities between the template in this volume and the templates in the other two books of the *Medical Toxicology Series*. This organizational consistency allows easy location of the appropriate information necessary for decisions regarding the sources, effects, regulation, and management of toxic exposures throughout the *Medical Toxicology Series*. General sections headings in this volume include, but are not limited to, physical properties, current and past exposure, dose effect, toxicokinetics, histology/pathophysiology, clinical response, dosimetry, health surveillance, and treatment.

Medical toxicology is a field often dependent on relatively weak scientific evidence (case reports, case series, retrospective analyses), resulting in the increased risk of perpetuating equivocal statements and even folklore. This volume provides the relevant evidence base to determine the clinical consequences and safety measures important for protection from radiation exposure in the workplace and environment. References are documented to validate the information and provide sources for further inquiry. Although this unique volume provides a medical toxicologist's perspective on radiation exposures, the coverage contains input from a variety of disciplines including other clinical specialties, public health physicians, and basic scientists.

The choice of topics in this volume reflects our desire to expand communication between medical toxicologists and related fields. Our hope remains that this interdisciplinary, evidence-based approach will increase communication between traditional clinical settings and fields aligned with medical toxicology including those in laboratories, academic settings, and regulatory agencies. We anticipate this approach will encourage more inquiry into the pathophysiology, clinical effects, biomarkers, treatment, and prevention of illnesses related to radiation exposures.

Robert B. Palmer, PhD, Editor

ACKNOWLEDGMENTS

I thank the following colleagues for their contributions to the quality, depth, and accuracy of *Medical Toxicology of Occupation and Environmental Exposures: Radiation*.

John Wiley & Sons' Staff

Dr. Andreas Sendtko, Senior Managing Editor, Physical Sciences Books, whose dedication and patient guidance guaranteed the accuracy of the printing process and the quality of these books.

Bob Esposito, former Senior Editor, made our *Medical Toxicology Series* a reality by believing in the importance of a highly detailed, structured series covering the expanding field of Medical Toxicology.

Michael Leventhal, Commissioning Editor, helped smooth the production process from submission to printing.

Summers Scholl, Executive Editor, whose contributions were essential to informing our medical audience of the key constituents of the *Medical Toxicology Series*.

Pomona Valley Hospital Medical Center

I admire the dedication and perseverance of the physicians, nurses, and the Emergency Department staff in times complicated by COVID-19 and variants, difficult medical problems, and complex social issues. In particular, I appreciate the support of the physician staff including Howard Friedman; Ivan Schatz; Richard Dorosh; Ken Nakamoto, past Vice President of Medical Affairs; Ken Moore, former Medical Director Emergency Department; and James Kim, Medical Director, Emergency Department.

UCLA Emergency Department Colleagues

I appreciate all our colleagues who shared their expertise and clinical experience at UCLA Conferences, especially Gregory W. Hendey, MD, Department Chair; Steven Lai, MD, Assistant Program Director, Olive View-UCLA; Richelle J. Cooper, MD, UCLA Emergency Department Research Director; Lynne B. McCullough, MD, UCLA ED Medical Director; Pamela Dyne, MD, Associate Program Director, Olive View-UCLA; Cynthia Koh, MD; Eric A. Savitsky, MD; Luis Lovato, MD, Informatics; David A. Talan, MD, former Chairman, Department of Emergency Medicine, Olive View-UCLA Medical Center, and Matthew Waxman, MD.

UCLA Librarians

Writing this book series was not possible without the support of the UCLA Biomedical Library, especially Juan Jaime, Access Services Manager, UCLA Science Libraries.

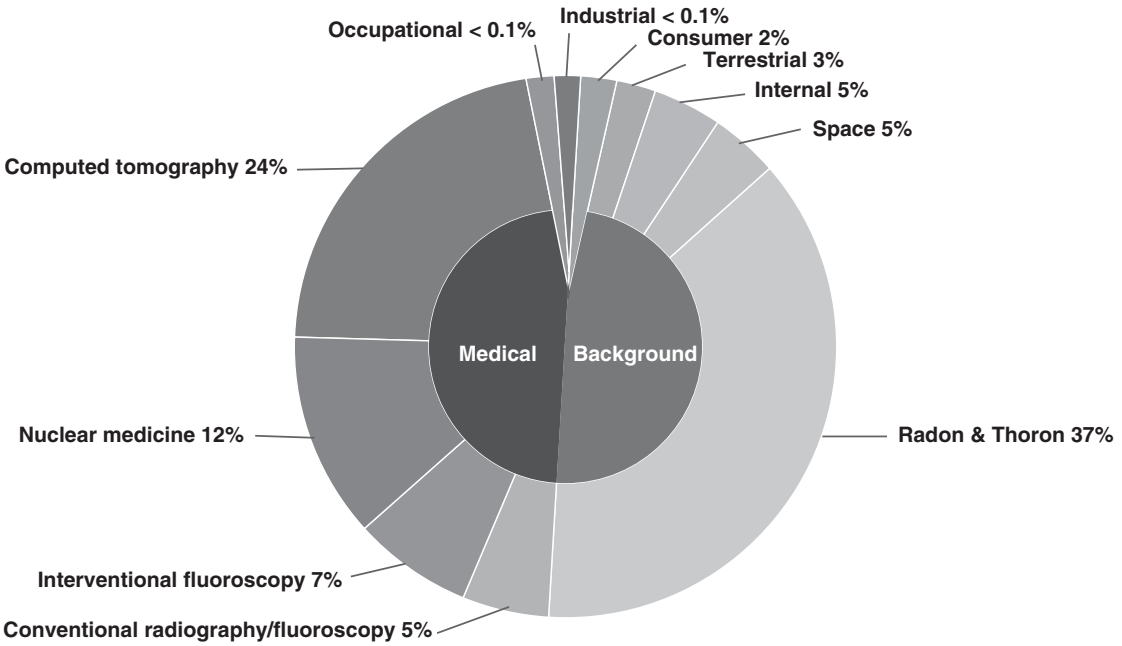
Chapter 37

RADIATION PHYSICS

HISTORY

Even though high-energy radiation has always permeated the universe, the discovery of electromagnetic waves did not occur until 1900.[1] Roentgen produced X-rays artificially from the bombardment of metal in evacuated tubes with electrons in 1895.[2] He named the radiation that penetrated screens of various thicknesses X-rays to denote the unknown nature of the radiation. The following year, Henri Becquerel detected radioactivity in the natural environment while investigating the role of phosphorescence of a glass tube.[3] Physicists and physicians began using X-rays to examine the bones, lungs, and other organs of patients. In 1903, Einstein determined the origin of energy transferred by radiation and the equivalency of matter and energy. Victor Hess discovered cosmic radiation in 1912 during a high-altitude balloon flight.[4] Currently, the average annual ionizing radiation dose in the United States from natural and artificial sources is similar (i.e., ~3 mSv).[5] Figure 37.1 displays the natural and artificial sources of radiation exposure in the United States.

PHYSICAL PROPERTIES



Radiation involves the transfer of energy from a source through a vacuum or a medium. Our senses detect some forms of radiation (e.g., visible light, sound, heat), whereas the wavelengths of some electromagnetic radiation are below (e.g., radio wave, microwave, radar) or above (e.g., X-rays, γ-rays, some UV light) those detectable by our inborn senses. Hence, our senses do not detect the hazardous forms of radiation in the ionizing portion of the electromagnetic spectrum. The two types of ionizing energy are: 1) electromagnetic radiation carried by discrete bundles of energy (photons) traveling as an electromagnetic wave, generated by the movement of electrical charges through an oscillating electromagnetic field or by nuclear decay; and 2) subatomic particles released from high-speed interactions of subatomic particles or from decay of atoms. Gamma-rays and X-rays from cosmic or human sources characterize the first form of radiation, whereas α-and β-particles characterize the latter form. Gamma-rays originate from radioactive decay of nuclei or galactic sources, whereas X-rays are released from electron orbitals. The biological effects of radiation depend on several factors beside the type of radiation, including the amount of energy transferred to living tissue, the geometry of the applied radiation, and the sensitivity of tissues to radiation damage.

Electromagnetic Waves

Photons comprised of electromagnetic waves possess no mass or electrical charge. Electromagnetic waves travel through the vacuum of space at the speed of light (3×10^8 m/second), whereas most other waves (e.g., sound) require a medium (gas, liquid, solid) to propagate. Wavelength (λ) is the distance of one full cycle of the oscillation of the electromagnetic wave as measured between adjacent troughs or peaks, whereas frequency is the number of cycles per second. Energy in electromagnetic radiation varies directly with frequency

FIGURE 37.1. Sources of radiation exposure in the United States. (National Council on Radiation Protection and Measurements).[5]

and inversely with wavelength; the higher the frequency, the greater the energy and the smaller the wavelength. Longer wavelength waves (e.g., radio waves) carry less energy than shorter ones. Shorter wavelength means higher frequency (e.g., γ-rays, X-rays), which transmits higher energy and greater penetration of tissue.

In SI units, the unit of energy is the joule (J); the energy (E) in a photon in joules is related to the frequency as defined by Equation 37.1.

$$E\ (\mathrm{J}) = hf \qquad \text{(Equation 37.1)}$$

where

h = Planck's constant (6.62607015 x 10^{-34} J/Hz or J-seconds),
f = frequency (Hz).

Wavelength (λ) and frequency (f) are inversely related as defined by Equation 37.2.

$$f = c/\lambda \qquad \text{(Equation 37.2)}$$

where

λ = wavelength,
f = frequency,
c = speed of light in a vacuum (299,792,458 m/second).

Both joules and electron volts are units of energy. The small amount of energy in photons necessitates the use of electron volts (eV). An electron volt is the energy acquired by an electron accelerating through a potential difference of 1 V; this value is equivalent to 1.602×10^{-19} J. Energy in electron volts (or joules) is directly related to frequency and inversely related to wavelength as determined by substituting Equation 37.2 into Equation 37.1 and rearranging it into Equation 37.3.

$$E\ (\mathrm{eV}) = hc/\lambda = 12{,}400/\lambda = 1.24\times10^{-6}/\lambda \qquad \text{(Equation 37.3)}$$

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

where

E = energy (electron volts, eV),
h = Planck's constant (4.136×10^{-15} eV × second),
c = speed of light (2.99792458×10^{8} m/second),
λ = wavelength (angstroms, 10^{-10} m).

Electromagnetic radiation interacts with biological tissues in the following three ways: 1) *transmission*, where the radiation passes through the tissue without interacting; 2) *reflection*, where the radiation deflects off the air/tissue interface back into space; and 3) *absorption*, where the radiation passes the outer layer and deposits the energy in the tissues. The frequency and wavelength determine the amount of energy released in the tissues. Injury to tissues results from the absorption and transfer of large amounts of energy to atoms and molecules in the path of the radiation.

Particulate Radiation

The second form of ionizing radiation is associated with high-velocity particles that are either electrically charged (e.g., α- or β-particles) or electrically neutral (e.g., neutrons). Linear accelerators, betatrons, and cyclotrons produce beams of particulate radiation by accelerating electrically charged particles, whereas fission in a nuclear reactor or the interaction of a charged particle and a target (e.g., accelerating deuterons into tritium) produce neutrons. The rate of ionization depends on charge, mass, and velocity. The higher the charge and the lower the velocity, the greater the potential for ionization. Emitted particles have very high energies; their energy is related to the mass of the particles by the Einstein Theory of Relativity, as displayed in Equation 37.4.

$$E \text{ (energy)} = mc^2 \qquad \text{(Equation 37.4)}$$

where

m = mass,
c = speed of light.

Whenever the nucleus emits an α- or a β-particle with a high-energy photon, the mass of the nucleus decreases by the amount (i.e., E/c^2) defined by Equation 37.4. Because of the equivalence of mass and energy, the mass of particles is usually expressed as energy (e.g., million electron volts, MeV) rather than units of mass.

Figure 37.2 displays the photon family of electromagnetic waves; photons are quanta of light or other electromagnetic radiation that have energy proportional to their frequency, but no mass. The non-photon family of elementary particles has charge *and* mass as displayed in Table 37.1. Each elementary particle exists in the following two states: matter and antimatter. The positron is the antimatter state of the electron. Although these two states are stable when separated, the collision of the two states annihilates both particles and transforms the matter into neutrinos and photons. In addition to photons, stable particles include electrons, protons, muon neutrinos, and electron neutrinos. Other members of the hadron family (mesons, hyperons) are extremely short-lived particles studied through the operation of high-energy accelerators. Electrons are the only important member of the lepton family of particles from a medical perspective. Although neutrinos are common, they do not contribute significantly to the medical effects of radiation.[1] The emission of neutrons usually occurs during the operation of nuclear reactors. Table 37.2 lists the physical characteristics of electromagnetic waves and particulate radiation.

Atomic Structure

All matter consists of elements (e.g., hydrogen, oxygen, lithium) composed of characteristic atoms. These atoms contain an extremely tiny nucleus (positively charged protons and electrically neutral neutrons of equal mass) and a relatively large surrounding area containing negatively charged, relatively low-mass (i.e., 1/2000 the mass of a proton) electrons. Consequently, atoms are mostly empty space. The nucleus contains most of the mass in an atom with each element described by the total number of protons and neutrons (*mass number*). Hence, the element and the mass number (e.g., uranium-238) characterize most atoms. The various species of atoms are called nuclides. Table 37.3 lists the terms used to define the structure of an atom.

There are 92 natural elements, ranging from hydrogen to uranium. For each element, the atomic number characterizes a specific number of protons along with a variable number of neutrons; the lightest element is hydrogen (one proton, hydrogen-1). An *isotope* is a nuclide of an element that possesses the same number of protons but different numbers of neutrons. Isotopes are different species of the same element. Hydrogen has the following three isotopes: hydrogen-1 (elemental hydrogen – 1 proton); hydrogen-2 (deuterium – 1 proton, 1 neutron); hydrogen-3 (tritium – 1 proton, 2 neutrons). Many isotopes are stable isotope species (i.e., atoms of a chemical element with the same atomic number but a different atomic mass or mass number) that do not undergo radioactive decay.

α-particle	4.034 (2 protons/2 neutrons)	+2

[a] AMU: The definition of an atomic mass unit is 1/12 the mass of an atom of carbon-12; the rest mass of a proton and neutron averages 1 AMU; [b] β-Particles are high-speed electrons emitted from the nuclei of decaying radioisotopes with the negative charge and small mass of an electron.

ELECTROMAGNETIC SPECTRUM

The electromagnetic spectrum emitted by natural and man-made sources ranges from the low frequencies and energy of radio waves to the high frequencies and energy of γ-rays and X-rays. Figure 37.2 demonstrates the electromagnetic spectrum. The frequency of electromagnetic waves in the electromagnetic spectrum is directly proportional to the amount of energy in the photons; thus, the greater the frequency, the higher the energy of the waves. The wavelength is inversely proportional to the amount of energy in the electromagnetic

Nuclides	Species of atom
Isotope	Nuclides of same element with different numbers of neutrons
Radionuclides	Unstable nuclides
Radioactivity	Emission of radiation
Decay	Transformation of radionuclide from unstable to stable atom

wave. The electromagnetic spectrum includes *non-ionizing* radiation (e.g., electric power, radio waves, microwaves, infrared, visible light, UVA, UVB, and UVC bands of UV radiation) and *ionizing* radiation (cosmic rays, X-rays, γ-rays). *Ionizing radiation* has sufficient energy to create charged particles (i.e., ions) by removing negatively charged electrons from the atom. This process creates: 1) a negatively charged electron; and 2) a positively charged atom. Human senses detect only the visible portion of the electromagnetic spectrum, except for the heat-generating absorption of infrared photons. Some nonionizing radiation (e.g., microwaves, ultrasound) can affect tissue by generating heat.

Ultraviolet (UV) radiation penetrates tissue poorly; therefore, UV light produces injury to the skin only by direct chemical interaction with molecules in the skin that possess high UV absorbance. Radiation with wavelengths shorter than visible light possesses the ability to displace electrons from their orbital shells; this portion of the electromagnetic spectrum produces ions in tissue.

Both γ-rays and X-rays possess sufficient energy to produce ionization and the formation of hydroxyl free radicals capable of damaging DNA and other biomolecules. Gamma-rays are photons emitted by unstable, radioactive nuclei; often these photons accompany the emission of β-particles from the same nuclei. X-rays are produced outside the nucleus when an electron transitions from a high-energy orbital to a lower energy state. Both X-rays and γ-rays travel great distances, easily penetrating cells of the body; however, man-made X-rays generally have somewhat lower energy (0.15 MeV) and comparatively less ability to penetrate tissue.

IONIZATION

Ionization occurs when electromagnetic radiation interacts with tissues to produce a loss or gain of electrons; this process involves sufficient energy to displace orbital electrons in atoms with a subsequent break in the chemical bonds holding the molecules together and the formation of free radicals (i.e., an atom or a molecule with a single unpaired electron in one orbit). The biological effect is the disruption of cellular molecules (primarily DNA) and consequent tissue damage. Typically, this reaction involves water or oxygen; the former usually involves the formation of hydroxyl radicals (i.e., OH, a highly reactive, oxidizing species). Radiation capable of causing ionization is called *ionizing radiation*. Direct radiation damage involves the deposition of a relatively large amount of energy (i.e., 33 eV) into a DNA sequence sufficient to disrupt the C=C bond and break the DNA strand. This type of reaction occurs most commonly with high linear energy transfer (high LET) from an α-particle. Indirect radiation damage results primarily from the interaction of a low linear energy transfer (low LET) photon with a water molecule, producing a free radical. The loss of an electron from the energy transfer causes the formation of an ion with high chemical reactivity and the capability to cause DNA strand breaks and cellular damage.

All forms of ionizing radiation penetrate matter and release energy by colliding with atoms and molecules. Ionization begins in a picosecond (10^{-12} seconds) with energy absorption, excitation, ionization, and free radical formation depending on the amount of energy deposited in the tissues. Disruption of biologically

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

important molecules (nitroxides, oxygen, thiols) occurs within a second; DNA damage (chromosomal aberrations, delayed cellular division, disruption of signal transduction, reduced cell proliferation, alteration of gene expression) follows in seconds to hours. The physiological effects (e.g., decreased growth factor, increased cytokines) develop in minutes to years. Cancer is a very late somatic effect. The physical and chemical reactivity of nonradioactive and radioactive isotopes of a given element are identical, except that the radioactive isotopes emit ionizing radiation.[7]

Indirect Ionization

Indirectly ionizing radiation passes through matter without interacting with electrons until the path is sufficiently long to produce a chance collision with components of an atom; this type of radiation includes both electromagnetic waves (X-rays and γ-rays) and some uncharged particles (neutrons and uncharged mesons). In contrast to directly ionizing particles, these uncharged particles do not lose energy to the surrounding medium until a chance collision occurs with an elementary particle in the atom. X-rays and γ-rays produce ionization indirectly by interacting with orbital electrons (Compton Effect or photoelectric effect) or nuclear forces (pair-production). At low energies (<0.05 MeV), the photoelectric effect predominates when the X-rays displace tightly bound electrons from the inner shell of the atoms. For photons with higher energies (0.1–10 MeV), the photon ejects the electron; however, the photons retain sufficient energy to continue exciting and ionizing molecules until the energy in the photon is sufficient only for photoelectric interactions. Photonuclear reactions occur when high-energy photons (>1.02 MeV) convert to a positron–electron pair that subsequently reacts with cellular processes.

Once freed from the atom, the ejected electrons then deposit energy in other atoms through electrical interactions with orbital electrons. Neutrons represent a special case where the main interaction is the collision of the neutron with the nucleus of an atom, typically hydrogen, carbon, or nitrogen. The kinetic energy of this collision displaces some nuclei, resulting in ionization of the tissue. Some very high LET particles may result from the fission process when neutrons interact with some nuclei.

Direct Ionization

Directly ionizing radiation includes free neutrons and all charged particles (e.g., α- and β-particles, electrons, positrons, deuterons, negative pi mesons, accelerator particles). This type of radiation produces ionization in all matter through which it traverses through its electrical interactions with orbital electrons of the atoms. The impulses of these charged particles act at a distance through the electrical forces between the charged particles and the electrons in the orbit of the atom. The amount of kinetic energy transferred to the tissues by this interaction depends on the velocity, charge, and mass of the particle.

$$\text{Kinetic energy} = \tfrac{1}{2} m v^2 \qquad \text{(Equation 37.5)}$$

where

m = mass,
v = velocity.

This energy transfer is measured by *linear transfer energy*. As the charged particles penetrate the medium, they lose kinetic energy until they stop. Consequently, higher initial kinetic energy of the charged particle causes relatively deeper penetration of the charged particle into the medium. Heavy, highly charged particles (e.g., α- and β-particles) lose energy rapidly in tissue, resulting in limited penetration.

Linear Energy Transfer

Linear energy transfer (LET) is the average amount of energy deposited along the path of the radiation through the tissue; the LET measured in keV/μm tissue is directly proportional to the amount of damage produced by the radiation. High-LET radiations include α-particles (LET >3.5 KeV/μm). This densely ionizing, high-LET radiation causes greater damage to the tissue than sparsely ionizing, low-LET radiation (γ-rays, X-rays) with track average LET ranging from ~0.2 to 3.5 keV/μm. LET increases with the square of the charge on the particle. Table 37.4 lists the characteristics of radiation quality as measured by the type of linear transfer energy.

TABLE 37.4. Characteristics of radiation quality as measured by linear transfer energy.

Low LET (γ-rays, X-rays)	High LET (α-particles, neutrons)
Sparsely ionizing	Densely ionizing
Modified by radical scavengers	Unaffected by radical scavengers
Dose rate dependent	Dose rate independent
Dose-response linear quadratic	Dose-response linear

Abbreviation: LET = linear transfer energy.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 37.5. Approximate relative biological effectiveness of ionizing radiation along with selected distances at which the radiation type penetrates selected media. Photon energy is measured in the half-value layer, reflecting the depth that absorbs one half of the incident radiation. The other radiation types are measured by the depth of penetration. (Adapted from Mettler and Upton).[6]

Radiation Type	Relative Biological Effectiveness	LET (keV/μ)	Air (cm at 1 MeV)	Water (cm at 1 MeV)	Concrete (cm at 1 MeV)	Lead (cm at 1 MeV)
γ-/X-rays[a]	1.0	0.3–10		9.6	5.0	0.9
β-particles	1–2	0.5–15	315	0.40		0.034
Neutrons	2–5	20–50				
α-particles	3–20	80–250	0.5	0.0072	—	—

Abbreviation: LET = linear energy transfer.
[a] Penetration measured in half-value layer rather than distance.

In general, the LET categorizes the relative biological effectiveness of different particles by the equilibration of the same biological effect for a given dose of relatively light particles (protons, helium ions) with different masses and charges. LET is a reasonable measure of radiation quality, but this quantity does not determine the total amount of damage because some high-LET radiation (α-particles) penetrates tissue poorly; therefore, this type of particle causes damage only in the area immediately adjacent to the α-particle. *Relative biological effectiveness* (RBE), as displayed in Table 37.5, is a general term that approximates the LET by comparing experimental ionizing radiation to X-rays and γ-rays (RBE ≅ 1). The RBE usually results from localized deposition of energy; this value may vary slightly between different tissues. Temperatures in tissue increase little (e.g., <0.002°C), even following the absorption of lethal doses of ionizing radiation).[6]

RADIOACTIVITY

The stability of a nuclide depends on the number of protons and neutrons, their configuration, and intra-atomic forces.[8] Typically, equal numbers of protons and neutrons produce stability. A *radionuclide* is an unstable atom that contains an excess of mass (protons, neutrons) or energy; radioactive materials emit ionizing radiation to reach nuclear stability. Elements with an atomic mass number of >200 are radioactive. Unstable atoms restore stability by emitting a particle (α or β) and/or energy in the form of electromagnetic waves (γ-ray, X-ray) during the process of radioactive decay. Activity (i.e., decay rate) is the number of disintegrations (or transformations) per unit time that occur in radioactive material, whereas specific activity refers to activity/mass (i.e., Bq/g or Ci/g). By convention, the curie (3.7×10^{10} disintegrations/second) is the conventional unit of activity, whereas the Becquerel (1 disintegration/second) is the metric (SI) measure of activity. Radioactive isotopes have identical chemical and physical properties (e.g., density, melting point, solubility) as nonradioactive isotopes of the same element; these nuclides chemically react identically within the body (e.g., the function of radioactive iodine and stable iodine is the same). Figure 37.3 displays the penetrating properties of radioactive particles and photons.

Alpha Particles

An *α-particle* is an energized helium nucleus (two protons, two neutrons, no electron shell) emitted by the heaviest nuclides in the periodic table (e.g., uranium, radium, plutonium) during their transformation to a stable nuclide. The emission of an α-particle reduces the atomic number by 2 and the atomic mass by 4. *Radioactive decay* is the process of a radionuclide converting to a stable nucleus; however, intermediate progeny may be more unstable (i.e., have a shorter half-life) than the parent form. When an unstable radionuclide spontaneously emits radiation, it is *radioactive*. The energy of an α-particle is relatively low (i.e., ~4–8 MeV) and unique to the α-particle compared with β-particles; the latter emits energy on a continuous spectrum with a maximum energy characteristic of the radionuclide. Alpha particles are easily shielded because they travel only a few centimeters in air; these particles are unable to penetrate paper or a few microns of epidermis.

Beta Particles

Radionuclides with excess neutrons usually emit negatively charged β-particles that convert neutrons to protons. Carbon-14 is a radionuclide that contains 6 protons and 8 neutrons in contrast to the stable nuclide carbon-12 (6 protons, 6 neutrons). Carbon-14 restores stability by emitting a β-particle and transforming into nitrogen (7 protons, 7 neutrons). Beta particles demonstrate a wide range of energies, depending on the specific radionuclide. These particles usually travel a few

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 37.3. Materials able to stop the penetration of α-particles, β-particles, γ-rays, X-rays, and neutrons. (Adapted from REAC/TS).

meters in air and penetrate a few millimeters into tissue. Consequently, plastic provides an effective shield from β-particles. Radionuclides with an excess of protons emit a positive charged electron called a *positron* that converts a proton to a neutron. Fluorine-18-deoxyglucose (FDG) is a positron-emitting radionuclide used for whole-body PET/CT medical imaging. Frequently, this transformation requires the release of energy.

Gamma- and X-rays

Gamma- and X-rays are photons (i.e., pure electromagnetic energy) that possess no mass. Electromagnetic energy emitted from *inside* the nucleus is called a *γ ray*. *Gamma radiation* travels many meters in air; lead is required to shield objects from γ-rays. *X-ray radiation* is electromagnetic energy emitted from *outside* the nucleus (e.g., radiation produced by bombarding high-energy electrons in an X-ray machine on a target). Some radioactive materials also emit X-rays. The penetration and shielding requirements (concrete, lead, steel) are similar for X-rays and γ-rays, as displayed in Figure 37.3.

Neutrons

Neutron radiation consists of neutral particles emitted from inside the nucleus, usually during fission reactions, with the exception of the decay of a few beryllium radionuclides. Neutrons exist at a wide range of energy levels and may travel extremely long distances in air. This type of radiation can induce radioactivity (neutron activation) when absorbed into the nuclei by stable elements (e.g., Al, Cl, N, Na, P, S); neutrons are the only type of radiation capable of creating radioactivity in other matter. Neutron radiation penetrates deeply; protection from this type of radiation requires special shielding (e.g., paraffin, water).

Positrons

Radioactive decay involving the emission of a positron (positive electron) is equivalent to converting a proton to a neutron. Conceptually, positrons are antiparticles of electrons; the interaction of an electron with a positron releases energy as two 511 keV photons at an angle of 180° to each other. Neutron-deficient nuclides (i.e., atoms with excess protons) typically emit positrons. The emission of a positron and neutrino converts a proton to a neutron; this reaction requires at least 1.02 MeV of energy.

RADIATION UNITS

Because the physical nature of radioactivity limits the application of ordinary measurements of mass, length, and weight, special units are necessary to describe the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. amount of radiation received by an individual. The International System of Units (SI) is usually preferred over the MKSA (meter-kilogram-second-ampere) system.[9] The major advantage of the SI system is the facilitation of international communication (the SI system is accepted by almost every country including the United States); the coherence and simplicity of this system do not require conversion factors for units derived from base and supplementary units.[10]

Exposure

The radiation dose measures the amount of radiation exposure. The absorbed dose is a quantifiable measure (milligray, mGy) whereas the equivalent dose (millisievert, mSv) and effective dose (mSv) are calculated for individual organs and the whole body, respectively, for use in radiological protection. Radiation exposure is synonymous with irradiation, typically defined as the amount of ionization per unit air mass resulting from X-rays or γ-rays. Measures of exposure quantify the amount of radiation in the environment rather than the actual dose received by an individual. In the older MKSA system, the roentgen (R) quantified the amount of ionization produced in air in terms of charge/mass of air (C/kg). This measure applies **only** to electromagnetic waves with energies 10 keV–3 MeV (e.g., X-rays, ~0.15 MeV; γ-rays, 0.01–3 MeV) in air; the roentgen does not apply to charged particles or other media (e.g., water). The roentgen approximates the old unit of absorbed dose (rad) only for γ-rays and X-rays; the roentgen typically overestimates the rad by a few percent.[11]

There is no SI equivalent to roentgen in the SI system. In this system, radiation fields can be specified by the *fluence* as defined by the number of particles or electromagnetic waves (photons) per unit area (e.g., per cm^2). The fluence rate (old term, flux) expresses the number of particles or photons/cm^2/second.

Absorbed Dose (D)

The absorbed dose is the fundamental radiation quantity that describes the deposition of energy delivered by ionizing radiation into an absorbing medium defined at a specific point or averaged over a mass of tissue. The absorbed dose (energy/unit mass, J/kg) usually refers to the average radiation dose transferred from the environment to the body (D) or a specific tissue (D_T); however, the absorbed dose throughout an organ or tissue is often nonhomogeneous, particularly when comparing the dose of specific internal organs. In general, the absorbed dose reflects the radiation risk to an organ or tissue only when the variation in uniformity is <50%.[6]

The transfer of energy by a photon results from: 1) the interaction of the photon with an atom that sets an electron in motion; and/or 2) the absorption of the kinetic energy from the high-energy photon into the surrounding tissue through excitation and ionization.[12] In SI units, the *gray* measures the latter effect in dimensions of energy per unit mass; the gray (Gy) is equivalent to the deposition of 1 J of energy/kilogram of tissue. The old metric equivalent of the gray is the rad. A rad (100 ergs/g) equals one centigray (cGy); 100 rad is equivalent to 1 gray.

Table 37.6 lists the units and conversion factors for the SI system and the old metric system, whereas Table 37.7 provides the conversion factors for SI (Gy, Sv, Bq) and conventional (rad, rem, Ci) units. The gray is an important unit for understanding and comparing the biological effects of radiation.

The unit for describing radiation fields is the *kerma* (**k**inetic **e**nergy **r**eleased in **ma**tter); this value is particularly suitable for high-energy photons and neutrons. This unit measures the initial stage of the energy transfer by summing all initial kinetic energy in a specific volume or mass released by the interaction of charged ionized particles, photons, and uncharged ionizing particles. The kerma measures the transfer of energy over a specific area, whereas the gray measures the absorption of energy over the whole path of the electron. Typically, the rad and kerma are interchangeable with the notable exception of calculating the doses for adult atomic bomb survivors; the organ dose/tissue kerma dose ranges from 0.4–0.7 for γ-rays and 0.12–0.55 for neutron radiation.[13] The absorbed dose may be smaller than the kerma for a given photon interaction because some energy may be lost through the emission of charged particles. Although the kerma is quantified by the gray, the kerma is equivalent to the absorbed dose only if: 1) the direction, energies, and number of charged particles are constant throughout the area; and 2) there is negligible production of secondary ionizing radiation (e.g., X-rays). Significant differences between the kerma and absorbed dose occur at the interface of two different materials (e.g., bone, soft tissue) and very high-energy radiation. Japanese atomic bomb survivors sustained multiple radiation exposures in addition to γ-rays and neutrons from the blast, including radioactive fallout from black rain and neutron activation in soils.

The equivalent dose (Sv, rem) is the absorbed dose (Gy, rad) times a quality factor (Q). For X- and γ-rays, the equivalent and absorbed doses are similar.

TABLE 37.6. SI and conventional radiation units.

Quantity (Symbol)	SI Units (Symbol)	Name (Symbol)	Conventional Unit (Symbol)	SI Unit Equivalent	Comment
Average energy/ ion pair	Joule (J)		Electron volt (eV)	1.602×10^{-19} J	
Power (P)	Joule/second (J/s)	Watt (W)	Watt (W)	equivalent	
Exposure (X)	Coulomb/kilogram (C/kg)		Roentgen (R)	1 C/kg = 3,876 R	Amount of radiation directed at a medium
Absorbed dose (D)	1 Joule/kilogram (J/kg)	Gray (Gy)	rad	0.01 Gy	Energy deposited in tissue
Dose equivalent (H_T)	Joule/kilogram (J/kg)	Sievert (Sv)	Roentgen equivalent man (rem)	0.01 Sv	Absorbed dose weighted for radiation quality
Effective dose equivalent (H_E)	Joule/kilogram (J/kg)	Sievert (Sv)			Dose equivalent weighted for radiation sensitivity of tissue
Collective effective dose equivalent	Joule/kilogram (J/kg)	Man Sievert (man-Sv)			Effective dose equivalent applied to a population
Fluence (ϕ)	$1/m^2$		$1/cm^2$	$10^4/m^2$	Number of particles (irradiance) from all angles crossing a unit area
Fluence rate (ϕ)	$1/m^2$ s	m^{-2}/s	cm^{-2}/s	$10^4/m^2$ s	Number of particles (irradiance) from all angles crossing a unit area per unit time. Flux is the old term for fluence
Kerma	Joule/kilogram (J/kg)	Gray (Gy)	rad	0.01 Gy	Mean kinetic energy transferred from charged particles to uncharged particles in a given mass
Linear energy transfer (LET)	Joule/meter (J/m)		Kiloelectron volt/ micrometer (keV/μm)	1.602×10^{-10} J/m	
Radioactivity (A)	1/second (1/s)	Becquerel (Bq)	Curie (Ci)	3.7×10^{10} Bq/second	Nuclear transformation rate

TABLE 37.7. Conversion table for units of radiation dose.

Unit	Symbol	Value	Conversion Factor
Gray	Gy	1 J/kg	100 rad
Sievert	Sv	1 J/kg	100 rem
Becquerel	Bq	1 disintegration/ second	2.7×10^{-11} Ci
Rad	Rad	100 erg/g	0.01 Gy
Rem	Rem		0.01 Sv
Curie	Ci	3.7×10^{10} disintegrations/ second	3.7×10^{10} Bq

Dose Equivalent (H_T)

The dose equivalent is a derived quantity used in radiation protection to calculate whole-body effective dose to an organ or tissue. The dose equivalent applies to reference models of stochastic effects using population group averages for radiation protection rather than risk assessment for individuals. The biological effectiveness of a given absorbed dose (Gy) varies depending on the type of ionizing radiation and a variety of other factors including the susceptibility of a given tissue. To compare all ionizing radiation doses in terms of potential biological damage, the ICRP developed dose coefficients (equivalent and effective dose/Bq intake) for formulating radiation protection guidelines using the process outlined in Figure 37.4. The primary purpose of the equivalent and effective dose is the summation of radiation doses from external and internal (i.e., absorbed radionuclides) sources to compare the stochastic risks of whole-body radiation exposure with dose limits, reference levels, and constraints; hence, these values apply

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 37.4. International Commission on Radiological Protection (ICRP) process for developing dose coefficients (equivalent and effective dose) based on modeling the absorption of the external radiation dose and adjusting the absorbed dose with radiation- and tissue-weighting factors. This method allows the summation of radiation doses received from external sources and intake of radionuclides. (Adapted from Harrison and Streffer).[15]

to radiological protection rather than determination of radiation-induced effects in epidemiology studies.[14] Calculation of the absorbed dose in Gy involves the use of biokinetic models to determine the total number of radioactive transformations within specific body regions and dosimetric models (e.g., anthropomorphic and mathematical phantoms) to determine energy deposition of important organs and tissues from transformations occurring in those regions. The dose equivalent normalizes the risk of a given absorbed radiation dose by accounting for the difference in the relative biological effectiveness of densely and sparsely ionizing radiation by using the Q or Quality factor as determined in Equation 37.6. However, the basis of the Q factor was a mathematical relationship to linear energy transfer (LET) rather than the relative biological effectiveness (RBE) of a radiation type.

$$\text{Dose Equivalent } (H_T) = (\text{absorbed dose}) \times (\text{quality factor}) \times (\text{distribution factor}) \quad \text{(Equation 37.6)}$$

Hence, Equation 37.6 did not account for the varying sensitivities of different tissues to the effects of ionizing radiation. Subsequently, the ICRP replaced the Q factor and the distribution factor in Equation 37.6 with the radiation weighting factor (w_R) by combining all factors other than absorbed dose to easily compare different types of radiation. The radiation-weighting factors adjust for the varying effectiveness of different radiation types/absorbed doses (Gy) to cause stochastic effects at low doses and dose rates. Thus, Equation 37.7 allows the comparison of radiation risks for people exposed to different radiation sources in different portions of their bodies.

$$H_T \text{ (sievert)} = D \text{ (gray)} \times w_R \text{ (no dimensions)} \quad \text{(Equation 37.7)}$$

TABLE 37.8. Radiation weighting factors related to external or internal ionizing radiation. (Adapted from Mettler and Upton).[6]

Radiation Type	Energy Range	Weighting Factor (w_R)
Photons	All	1
Electrons/muons	All	1
Neutrons	<10 keV	2.5[a]
	10–100 keV	2.5–7.5[a]
	>100 keV–2 MeV	7.5–20[a]
	>2–20 MeV	20–7.5[a]
	>20 MeV	7.0–2.5[a]
Protons/charged pions		2
α-particles, heavy nuclei		20

[a] Ranges represent a continuous function of neutron energy rather than discrete values.

Table 37.8 lists the radiation weighting factors symbolized as w_R for each type of ionizing radiation. The dose equivalent is designed to protect individuals from radiation; therefore, the dose equivalent is the basic unit in radiation protection. The dose equivalent is a better measurement of radiation risk than the absorbed dose.[16]

For X-rays, γ-rays, and β-particles, the rad and the rem are equivalent to the gray (Gy) and the sievert (Sv), respectively. 1 Gy = 100 rad and 1 Sv = 100 rem. Alpha particles cause 20 times greater biological damage than an equal absorbed dose of γ-rays or β-particles; therefore, the quality factor for α-particles is 20. The dose equivalent (sievert) is not a measured quantity; the sievert normalizes the damage caused by different types of ionizing radiation. Table 37.6 demonstrates the conversion factor for the older unit of absorbed dose (rem).

Effective Dose Equivalent (H_E)

Typically, the body does not receive the equivalent dose in a uniform manner; therefore, the *effective dose equivalent* (effective dose) was created by the ICRP to equate

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the radiation risk to a specific part of the body relative to the risk of whole-body radiation for the purpose of setting radiation protection limits (i.e., annual radiation exposure to ionizing radiation or radionuclides for workers and the public). Consequently, the effective dose is a derived rather than a physically measurable quantity. This quantity includes multiple factors including radiation types, tissue radiosensitivities, population characteristics, and biological endpoints.[17] The ICRP recommends the use of the abbreviated term *effective dose* to describe the effective dose equivalent as the product of the equivalent dose (H_T) and the weighting factor (w_T) summed over all tissues, as displayed in Equation 37.8. The tissue weighting factors adjust for the contribution of individual organs and tissues to the age- and sex-averaged overall detriment from cancer and hereditary effects. The effective dose is a broad risk measure for developing a fatal malignancy irrespective of the type and energy of the radiation or the distribution of the radiation in the body. The effective dose provides a measure of the risk of radiation-induced adverse effects for protection purposes rather than an assessment of individual doses or an estimation of the hypothetical number of cancer cases in the exposed population.[15,18] Consequently, the effective dose applies to reference models rather than predictions of future cancer risks in individuals.

$$\text{Effective Dose } (H_E) = \sum H_T \times w_T \quad \text{(Equation 37.8)}$$

where

H_E = effective dose (Sv),
H_T = dose equivalent of a tissue,
w_T = tissue weighting factor for the type of ionizing radiation and tissue (dimensionless).

For evaluation of the effective dose from the incorporation of radionuclides, the ICRP uses the *committed effective dose* (E_t), where t is the integration time in years following the intake of the radionuclide. Because the sensitivity of organs in the body to ionizing radiation varies, the biological effect of an absorbed dose differs depending on the time of delivery (equivalent doses received over a long period of time are less harmful than the same dose delivered at one time) and the tissue receiving the absorbed dose. The effective dose provides the basis for radiation protection assessments; only organ weighting factors recommended by the International Commission on Radiological Protection (ICRP), as listed in Table 37.9, should be used for assessing radiation risk of radionuclides.[16] The effective dose does not provide information on the risks of specific cancer types or deterministic effects. The ICRP values apply to reference values rather than risks in an individual or population with no assessment of uncertainties related to individual characteristics.[15]

TABLE 37.9. International Commission on Radiological Protection recommendations on tissue weighting factors (w_T). These values are averaged across all ages and genders; consequently, these values do not necessarily apply to radiosensitive subpopulations (e.g., children, young women). Additionally, the values reflect the observed late stochastic effects rather than short-term adverse tissue reactions, which are important in the use of therapeutic radiotherapy. (Adapted from Wrixon).[18]

Tissue Group	Tissue Weighting Factor (w_T)	Group w_T Value
Adrenal glands, bone marrow (red), breast, colon, extrathoracic region, gallbladder, heart, kidneys, lung, lymph nodes, muscle, oral mucosa, pancreas, prostate[a], small intestine, spleen, stomach, thymus, uterus[a]	0.12	0.72
Gonads	0.08	0.08
Bladder, esophagus, liver, thyroid gland	0.04	0.16
Bone surface, brain, salivary glands, skin	0.01	0.04
Total		1.00

[a] When present.

The effective dose accounts for different radiosensitivities to the development of malignancy in various tissues by using the committee-selected weighting factors listed in Table 37.9. Weighting factors include substantial uncertainties including the linearity of the dose-response at low radiation doses.

The effective dose equivalent is the amount of radiation required to produce the same risk as the application of ionizing radiation to the whole body rather than specific parts or organs within the body.[19] Because the quality factors are approximations used for radiation protection, these factors contain built-in biases to protect radiation workers.[11] Consequently, epidemiology studies using effective dose equivalents may underestimate the true risk of a given exposure depending on the accuracy of the quality factors. Effective dose equivalents were not calculated for studies completed before 1977, when the old system did not calculate weighted risks.

The effective dose originally reflected the risk of fatal cancer within the first two generations of offspring in the working population. The incidence of curable cancer is not considered in the risk calculation;

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

hence, extrapolation of these risk factors to the general population does not account for the difference in ages between the general population and the working population. Additionally, the effective dose equivalent does not include the development of curable cancer or the appearance of hereditary harm beyond the second generation of offspring in the general population. Frequently, the effective dose equivalent is abbreviated as the dose or the effective dose and reported in units of the sievert; this value has the same dimension (J/kg) as the gray.

Collective Effective Dose Equivalent (Man Sievert)

For epidemiological purposes, the *collective effective dose equivalent* is a measure of the total radiation to a specific population. The unit is the man sievert (man Sv) calculated by multiplying the effective dose equivalent by the number of people exposed to the effective dose equivalent. Similar to dose uniformity, collective dose implies linearity between radiation dose and adverse effects with no threshold. Additionally, this concept applies only to low radiation doses (e.g., background radiation), as adverse effects differ dramatically when the radiation dose received by the population is applied to one person.

Radioactivity (Becquerel)

Radionuclides decay occurs by the emission of radiation in the form of particles and photons. *Activity* is a measure of decay in units of disintegrations per second. The *Becquerel* corresponds to one disintegration of the radionuclide/second. The radioactivity of plutonium-239 is expressed in millions of Becquerels (i.e., megabecquerel, MBq); the activity of 1 g of this radionuclide is 2,000 MBq because it emits 2,000 α-particles each second. The emission rate of a particle is equivalent to its activity **only** when each disintegration involves that particle. Many radionuclides eject α-and β-particles in addition to photons; hence, the number of α- or β-particles released by the radionuclide would be less than the activity of the radionuclide.

The time required for a radionuclide to lose half of its activity is called the *physical half-life*. The physical half-life is unique to every radionuclide, varying from milliseconds to millions of years; the physical half-life is constant throughout the life of the radionuclide. The physical half-life of uranium-238 is 4,470 million years. The *biological half-life* is the time required to eliminate ½ the dose of the radionuclide from the body. Biological half-lives are shorter for radionuclides (iodine, cesium, tritium) that deposit in soft tissue compared with radionuclides (plutonium, radium, strontium) primarily entering bone. The effective half-life is a measure of the transit time of the radionuclide in the body as defined by Equation 37.9:

$$1/\text{effective}\ t_{1/2} = 1/\text{biological}\ t_{1/2} + 1/\text{physical}\ t_{1/2} \quad \text{(Equation 37.9)}$$

The effective half-life is always shorter than the biological half-life or the physical half-life. This value accounts for the situation where a radionuclide with a long physical half-life is eliminated quickly or absorbed slowly.

Chapter 38

COSMIC RADIATION AND RADON

COSMIC RADIATION

HISTORY

Human exposure to ionizing radiation began with the beginning of evolution. In September 1859, telegraph systems failed in Europe and America as auroras filled the sky from a geomagnetic storm that released high-energy particles during a solar flare. Victor Hess used three ionization chambers to detect increasing radiation as he ascended to 5,300 m during a historic balloon flight in 1912. Later, Robert Millikan's discovery of his law of motion of a particle entering the earth's atmosphere and falling toward the earth, along with his studies of ionization chambers, convinced him that the radiation penetrating the atmosphere was electromagnetic from above rather than below. He called this radiation cosmic rays in a paper published in 1925.[1] In the same year, Arthur Compton correctly determined that cosmic radiation was primarily composed of charged particles. These investigations helped demonstrate the extraterrestrial source of cosmic radiation and the variation of this radiation with latitude. Only since the 20th century has human activity (e.g., uranium mining, air travel, nuclear technology) added to the natural burden of radiation.[2] The development of commercial supersonic aircraft during the 1960s with cruising altitudes of 19 km required monitoring of the effective radiation dose of flight crews and passengers. The first commercial supersonic airliner, the Russian Tupolev-144, descended to lower altitudes when the effective dose rate exceeded 300 μSv/hour.[3] By the early 1990s, natural radiation sources represented ~87% of the annual effective dose rate (2.5–3.6 mSv) compared with 13% for artificial (human) sources.[4]

PHYSICAL PROPERTIES

Cosmic radiation refers to high-energy extraterrestrial particles striking the earth's surface and particles (e.g., radionuclides) formed by the interaction of extraterrestrial particles with the atmosphere. The sources of these particles are galactic (outside the solar system) and solar (from the sun). Galactic particles are mostly protons (i.e., ~85%) with energy fluence up to 10^{20} electron volts (eV), whereas protons with energies $<10^6$ eV comprise 99% of solar particles. The two mechanisms of irradiation from natural sources are internal and external. Cosmic rays and terrestrial γ-rays are the main external causes of natural radiation, whereas ingestion of radionuclides from cosmic and terrestrial origins is the major internal source of natural radiation.[5] Terrestrial γ-ray flashes presumably result from the collision of atoms in the atmosphere and electrons accelerated to near the speed of light by lightning; these events last a few milliseconds with energies up to 20 MeV and are not related to cosmic radiation.[6] High-energy protons are the main constituent of those extraterrestrial particles that originate from the sun (i.e., solar particles) and sources outside the solar system (i.e., galactic particles). Solar and galactic particles are primarily high-energy muons and electrons; these secondary particles produce an absorbed dose similar to β- and γ-radiation generated by terrestrial radionuclides.[7]

TABLE 38.1. Estimated annual worldwide effective dose rate. (United Nations Scientific Committee on the Effects of Atomic Radiation).[8]

Source	Average Annual Worldwide Dose (mSv)	Typical Annual Range of Individual Doses (mSv)
Natural sources		
Inhalation (radon gas)	1.26	0.2–10
External terrestrial	0.48	0.3–1
Ingestion radionuclides	0.29	0.2–1
Cosmic radiation	0.39	0.3–1
Total natural sources	2.4	1–13
Human sources[a]		
Medical imaging (excluding radiotherapy)	0.6	0–several tens
Atmospheric nuclear testing	0.005	Higher doses near test sites
Occupational exposure	0.005	~0–20
Total human sources	0.6	0–several tens

[a] Contributions from nuclear power plants and radiation accidents (e.g., Chernobyl) are too small and geographically localized to affect the total dose of radiation.

EXPOSURE

The estimated annual worldwide effective dose rate for natural radiation is 2.4 mSv with a typical range of 1–13 mSv; some populations may receive up to 10–20 mSv.[8] Radiation doses for nuclear medicine are substantially higher in developed countries. Table 38.1 displays the estimated annual worldwide effective dose rates for natural and human sources of radiation.

Cosmic Rays

On the earth's surface, the major variation in the energy delivered by cosmic radiation results from changes in altitude (i.e., doubling every 2,000 m) and latitude (i.e., doubling between the equator and pole). The atmosphere attenuates the energy of cosmic rays with the intensity decreasing linearly ~1.5 μSv/km at 16 to 80 km above the earth's surface.[9] The solar cycle accounts for ~10% of the variation in the radiation from cosmic rays.[10] Galactic cosmic rays reach their maximum intensity during the least active portion of the solar cycle and their minimum intensity during maximum solar activity. The magnetic fields of the earth also provide a partial shield against the charged particles.

Cosmic radiation entering the earth's atmosphere consists of protons (86%), α-particles (11%), and electrons (2%), with heavier nuclei accounting for the remainder; the energy spectrum of cosmic radiation ranges from 10^8 to over 10^{20} eV.[11] With the exception of high-energy radiation (i.e., $>10^{15}$ eV) that probably originates in supernovas, most cosmic radiation is created in our galaxy.[12] Our atmosphere attenuates radiation from galactic (i.e., outside the solar system) and solar particles (i.e., radiation from the sun) by >1,000-fold times.[5] The amount of cosmic radiation modulated by our atmosphere also depends on the geomagnetic field of the earth with minimum dose rate and intensity at the equator and maximums near the geomagnetic poles. Table 38.2 compares the composition of cosmic radiation at 12 km above the minimum and maximum locations of the earth's geomagnetic field where there is no significant solar radiation.

TABLE 38.2. Contribution of various components of cosmic radiation to the ambient dose equivalent comparing geomagnetic equator (minimum) with polar latitude (maximum), assuming an altitude of 12 km and solar minimum. (Modified from European Radiation Dosimetry Group (EURADOS), European Commission).[9]

Component	Equator (% of Total)	Polar Latitude (% of Total)
Muons	5	3
Photons	8	5

Although no deflection of cosmic radiation occurs at the geomagnetic poles, the atmosphere deflects most extraterrestrial particles with an energy of $<2\times10^{10}$ eV within the first several hundred g/cm of atmospheric thickness at the geomagnetic equator. The galactic radiation flux is relatively constant over time; however, strong disturbances of local magnetic fields caused by solar flares produce ~3-fold variation in total galactic particle density. This change in the galactic particle flux occurs over the 11-year cycle of solar flares, varying inversely with the intensity of the solar flares. Modeling solar events is complicated by the large uncertainties (e.g., >5-fold) involved in determining their contribution. Typically,[13] the estimation requires retrospective use of ground-level neutron monitors and rarely on-board measurements.

Cosmic rays interact with the atmosphere producing pions (π mesons), protons, neutrons, and low-Z nuclei; neutral pions decay to high-energy photons that generate electrons and more photons, whereas charged pions decay to muons. Muons are the dominant particle at low altitudes (<6 km), whereas electrons and neutrons are the primary components at higher altitudes as demonstrated in Figure 38.1. Variation in the intensity of the radiation flux also occurs at different locations on the earth. The earth's magnetic field strongly influences the cosmic neutron flux with neutron fluence rates at sea level near the equator at 20–25% of the polar rate, primarily changing between 50° and 20° latitude. The contribution of neutrons is greater (i.e., ~75%) at the poles compared with ~50% at the equator. At sea level, muons comprise ~70% of the dose equivalent, photons/electrons contribute ~15%, and neutrons ~10%; charged pions and protons account for ~1–2% of the dose equivalent at sea level.[11]

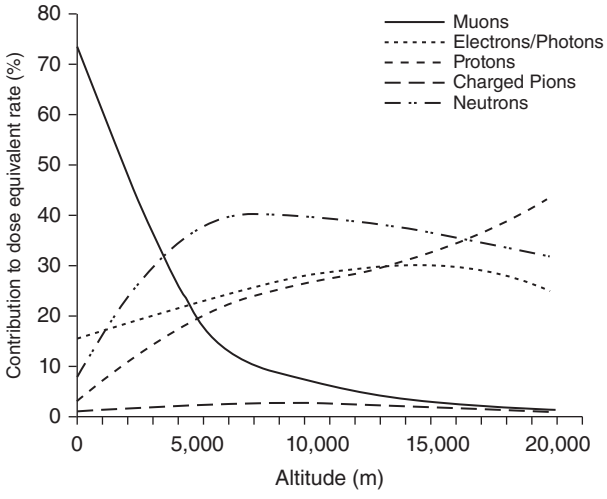

FIGURE 38.1. Components of dose equivalent rate from cosmic rays at various altitudes. (United Nations Scientific Committee on the Effects of Atomic Radiation).[11]

Cosmic Radionuclides

Although cosmic rays produce at least 14 radionuclides in the atmosphere, ranging from ^{3}H to ^{81}Kr, only 4 cosmic radionuclides contribute significantly to the cosmic radiation dose in the general population including ^{3}H, ^{7}Be, ^{14}C, and ^{22}Na. Radiocarbon decays naturally in the atmosphere with a half-life of 5,700 ± 30 years.[14] Fossil fuels are millions of years old and contain stable carbon isotopes (^{12}C, ^{13}C) rather than ^{14}C. The introduction of carbon from the combustion of coal and oil along with alterations in CO_2 cycling between terrestrial, oceanic, and atmospheric carbon reservoirs reduce the specific activity of carbon in airborne carbon dioxide because fuels contain little ^{14}C.[12] Alterations of the ^{14}C/C ratio impair the ability of radiocarbon dating techniques to accurately determine the age of substances.[15]

Primordial (Terrestrial) Radionuclides

The ubiquitous radionuclides of terrestrial origin involve radionuclides with half-lives comparable to the age of the earth and their decay products; irradiation from this material consists primarily of γ-radiation from the ^{238}U series, ^{232}Th series, and ^{40}K. Ingestion of these radionuclides results in internal irradiation. Inhalation exposure to primordial radionuclides mainly involves ^{222}Rn from the ^{238}U series; the effective dose from inhaling ^{220}Rn is substantially less than ^{222}Rn because of the short half-life (i.e., 55 seconds) of the former decay product of the ^{232}Th series. The contribution of other primordial radionuclides (e.g., ^{87}Rb, ^{138}La, ^{147}Sm, ^{176}Lu, ^{235}U) to effective dose rates is small.[11]

DOSE EFFECT

Total background radiation exposure for the general US population is 2–3 mSv with annual occupational limits of 50 mSv in the United States and 20 mSv in Europe. The absorption of 1 Sv (1,000 mSv) during a radiation incident produces nausea, vomiting, diarrhea, skin vesicles, and increased cancer risks.[16] The population-averaged value for the cosmic effective dose equivalent depends on the altitude, time spent indoors, shielding, and duration of aircraft flights.[5] The estimated annual dose equivalent in the US population is ~0.25–0.26 mSv. Table 38.3 lists the estimated annual US

dose equivalent rate from cosmic radiation for various tissues. As displayed in this table, inhaled radionuclides (i.e., radon) dominate the exposure to cosmic radiation, affecting primarily the lungs.

Cosmic Rays

Cosmic rays contribute ~30–50% of the total radiation dose from external environmental sources. In the United Kingdom, the annual effective dose equivalent (effective dose rate) is 0.3 mSv with muons accounting for 0.28 mSv and neutrons contributing 0.02 mSv.[5] The variation in this dose rate is much smaller in the United Kingdom than in the United States because the United Kingdom is relatively flat compared with the United States. The annual world population average effective dose rate from charged particles (primarily muons) and photons is 0.28 mSv, whereas the global average effective dose rate for neutrons is 0.10 mSv accounting for altitude and latitude effects.[11] The composition and intensity of the radiation flux and the effective dose rate from cosmic rays vary with altitude, latitude, and solar cycle, as displayed in Figure 38.2. Although solar events may double the effective dose rate during short periods, the overall effect on annual exposure rates for airplane crews is minimal.[17] The galactic effective dose equivalent rate (effective dose rate) is ~2 times greater over the geomagnetic pole than the geomagnetic equator.[18] Shielding structures (e.g., airplanes, houses) do not affect the absorbed radiation dose because muons penetrate these structures easily.

Environmental Exposure

Passengers receive more cosmic rays flying in an airplane than standing on the ground, especially during polar flights; however, an occasional airplane flight contributes a very small amount of radiation compared with natural background sources. The typical cruising altitude of commercial flights exceeds 10,000 m, whereas the effective dose rate can range up to 7 μSv/hour (i.e., >150-fold greater than exposure to cosmic radiation at

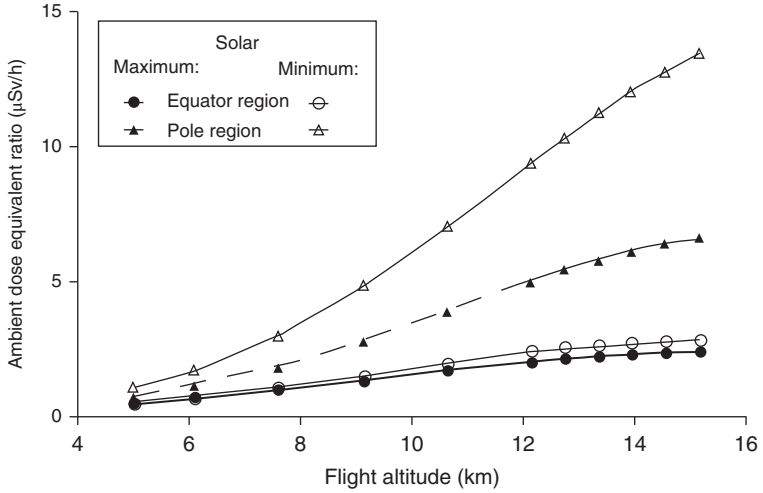

FIGURE 38.2. Ambient dose rates (μSv/hour) as a function of altitude, solar maximum/minimum, and polar/equatorial regions. One kilometer equals 3,280.84 feet. (Di Trolio et al.).[19]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

sea level).[20] The average dose equivalent rate for cosmic and terrestrial radiation on the ground in the United States is ~0.06 μSv/hour compared with a dose equivalent rate of 6 μSv/hour from cosmic rays at 35,000 ft, ranging from 2–10 μSv/hour, depending on altitude, latitude, and solar activity.[18] The sun typically emits particles with energies too low to contribute to the annual effective dose rate even during flight; however, rare, unpredictable solar events may produce high-energy particles that can increase the dose equivalent rate by ~10-fold on aircraft at 41,000 ft (0.1 mSv/hour).[21] The effective radiation dose from spending a 10-day vacation in a high mountain region is the same dose of cosmic radiation a passenger receives flying from London to New York.

Occupational Exposure

The effective radiation dose rates from aircraft flights depend on altitude, geomagnetic latitude, and the solar cycle. Table 38.4 lists the estimated dose equivalents from cosmic radiation during various air routes to and from selected US airports. Frequent flyers (e.g., business/government personnel) and most crewmembers receive annual dose equivalents near 1 mSv (~200 hours exposed to ~5–6 μSv/hour), whereas some crewmembers flying frequent polar routes may receive radiation doses several times higher depending on the duration of the flights.[7] Flight times in the United States typically are ~900 hours compared with ~600 hours for European crewmembers. Except in unusual circumstances, airplane crewmembers typically receive an effective annual dose rate of <10 mSv with exposure conditions much more uniform than in the nuclear industry. Estimates of the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) for the annual effective dose rate of airplane crewmembers range from a few mSv (1.2–5 mSv) up to ~6–7 mSv, depending on flight routes and hours.[22] The higher values in Europe apply to Denmark, Finland, and Germany. Use of more recent radiation weighting factors reduces these doses by ~30%.

Astronauts in low earth orbit receive radiation from galactic cosmic radiation, solar energetic particles, electrons, and protons in the earth's radiation belts, and, to a lesser extent, neutrons and protons resulting from the interaction of cosmic radiation with the earth's atmosphere. The typical whole-body dose equivalent

Committed effective dose/year with weighting factors for age (infants, 0.05; children, 0.30; adults, 0.65).

received by an astronaut during a mission ranges from 1–10 mSv. Although no large solar events have occurred during these missions, radiation from solar flares may increase this dose by 100-fold.[1] Typical daily dose rates at the ~300 km altitude of the International Space Station range from ~35 μGy at the solar maximum to ~140 μGy at the solar minimum.[17]

Cosmogenic and Primordial Radionuclides

Radiation doses from cosmogenic radionuclides are substantially less than those from primordial radionuclides. The estimated annual committed effective dose rates (committed effective dose equivalent or effective dose rates) for the main cosmic radionuclides are as follows: ^{3}H, 0.01 μSv (0.00001 mSv); ^{7}Be, 0.03 μSv (0.00003 mSv); ^{14}C, 12 μSv (0.012 mSv); and ^{22}Na, 0.15 μSv (0.00015 mSv).[11] For external exposure to γ-radiation from terrestrial (primordial) radionuclides, the estimated population-weighted average annual effective dose rate is 0.48 mSv (indoors, 0.41 mSv; outdoors, 0.07 mSv). Results for individual countries typically range from 0.3—0.6 mSv, with outdoor rates lower than indoor rates depending on the percentage of wood-frame construction. External dose rates may increase by 10–100-fold in areas of thorium-containing monazite sand deposits (e.g., Madras and Kerala, India; Guarapari, Brazil), radium-containing hot springs, and volcanic soils. The concentration of ^{40}K in the soil is highly variable (i.e., 0.3–4.5%) with this radionuclide comprising 0.0118% of naturally occurring potassium.[12] The estimated annual effective dose rate from the ingestion of ^{40}K is 0.165 mSv for adults and 0.185 mSv for children. The concentrations of uranium and thorium radionuclides in food vary significantly because of differences in agricultural practices, climatic conditions, and baseline background values. Table 38.5 lists the estimated annual effective dose rate for the ingestion of uranium and thorium series radionuclides by the general population including infants and children; the values are given in μSv (0.001 mSv) based on UNESCAR calculations.

The inhalation of short-lived progeny of ^{222}Rn and ^{220}Rn provides the main exposure pathway for the lungs because of pulmonary energy deposition by α particles and smaller amounts of β-particles and γ-rays. The effective dose rates for these two radionuclides in outdoor air are highly variable secondary to diurnal and climatic changes with the values much smaller than indoor values. The estimated annual effective dose rate for outdoor exposure is 0.095 mSv compared with 1.01 mSv for indoor exposure.[11] Inhalation of these radionuclides from the uranium and thorium series is dominated by ^{210}Pb and ^{210}Po with these two radionuclides accounting for 70% and 20%, respectively, of the total committed effective dose rate of ~0.12 mSv.

CLINICAL RESPONSE

Environmental Exposure

The risk of developing terminal cancer from exposure to cosmic radiation is sufficiently small to complicate the detection of increased mortality in epidemiology studies.[23] Table 38.6 demonstrates the size of a cohort necessary to detect a statistically significant increase in the incidence of leukemia-related deaths from cosmic radiation. These data assume a power of 90% and an α of 0.05. These data indicate a cohort size of 1 million persons is necessary to detect a 60% increase (risk ratio = 1.6) in leukemia-related deaths at an excess annual dose rate of 20 mSv; the estimated annual effective dose rate from natural background radiation is ~2.5 mSv.[7]

Most aircraft passengers are occasional flyers; these individuals absorb negligible amounts of cosmic radiation during flight compared with total radiation exposure.[20]

Occupational Exposure

Epidemiological data demonstrate no clear relationship between annual flight duration, corresponding doses of cosmic radiation, and an excess risk of radiation-related cancers. Some studies report an increased incidence

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 38.6. Risk ratios, mortalities, radiation doses necessary to document a significant increase in leukemia mortality, given various sizes of control and exposed populations in a cross-sectional study. (Adapted from National Council on Radiation Protection and Measurements)[7]

Length of Observation (person-years)	Required Risk Ratio[a]	Required Annual Mortality/ Million Exposed (Total/Excess)[a]	Excess Dose Rate (mSv/year)[a]
1,000	124	8,700/8,600	4,300
10,000	15	1,070/1,000	500
100,000	3.3	230/160	80
1,000,000	1.6	110/40	20

[a] Expected leukemia mortality is 70/year/1 million persons with a lifetime risk factor coefficient of 2/year/million persons exposed to 1 mSv/year.

of certain types of cancer among flight crews, whereas other studies fail to demonstrate similar associations. Cohort studies of aircraft crews suggest excess risks of melanoma and nonmelanoma skin cancer, whereas the association with breast and brain cancers is weak. Other risk factors (e.g., lifestyle) and study biases potentially account for the excess risk of these cancers (e.g., skin cancers).[19,24] Increased incidence of skin cancers among airline cabin crews is the most consistent positive finding in epidemiological studies of pilots and cabin crews. A UK study of flight crewmembers did not detect an elevated incidence of skin cancers or a trend of increasing skin cancer rates with flight time.[25] In this study of 19,494 flight crews and air traffic control officers (controls), the standardized incidence ratio for skin melanoma was 1.87 (95% CI: 1.45–2.38) for members of the flight crew compared with 2.66 (95% CI: 1.55–4.25) for air traffic controllers (controls) based on cancer rates in the general UK population. The elevated SIR resulted from lifestyle (i.e., easily sunburned skin, sunbathing to obtain a tan) based on reviews of medical records and postal questionnaires (50% response rate). The overall incidence of cancer was relatively low in both groups, primarily due to lower prevalence of smoking in these groups compared with the general UK population.

Although some studies report a higher incidence of breast cancer among female cabin crews,[26] most other studies failed to demonstrate an association between breast cancer incidence and cumulative estimates of cosmic radiation, sleep rhythm disruptions, or time zones crossed.[27,28] Neither cosmic radiation nor circadian rhythm disruption explain the elevated breast cancer risks in the suggestive studies. Increased nulliparity, height, and alcohol intake among female cabin crewmembers compared with the general population may account for some of the differences in the studies.[29] In a pooled cohort study of 93,771 airplane crewmembers from 10 countries followed for a mean of 21.7 years (2.0 million person-years), the overall mean mortality rate was strongly reduced in male cockpit (SMR = 0.56, 95% CI: 0.54–0.58) and female cabin crews (SMR = 0.73, 95% CI: 0.69–0.77).[30] The mortality from radiation-related cancers was also reduced in male cockpit crews (SMR 0.73, 95% CI: 0.62–0.85) but not in cabin crews (SMR ≅ 1). Mortality from female breast cancer (SMR = 1.06, 95% CI: 0.89–1.27), leukemia, and brain cancer was similar to that in the general population. The study suggested increased mortality from malignant melanoma, particularly in male cockpit crews (SMR = 1.57, 95% CI: 1.06–2.25). Interpretation of these studies is complicated by the healthy worker effect; airplane crewmembers typically have lower rates of hypertension, obesity, and smoking along with increased physical activity when compared to the general population. Additionally, some studies suggest diagnostic scrutiny may have a stronger influence on melanoma incidence than overall UV radiation.

DOSIMETRY

Analytical Methods

The complexity of particles and energy in cosmic radiation complicates the quantitation of effective dose rate during flight; instruments designed to measure this radiation are bulky and have limited accuracy. Consequently, validated computer models are available to estimate the effective dose rate of aircraft crews and passengers with accuracy of 20% within the measured median.[3] The International Commission on Radiation Protection and Measurements recommends the use of validated computer models to retrospectively estimate individual radiation doses from airplane flights instead of measurement devices (e.g., dosimeters).[3] These programs divide the route of the flight through the atmosphere into cubes with the mean effective dose rate in each cube dependent on the altitude, geomagnetic latitude, and solar modulation. Decreasing solar activity allows more galactic radiation to reach the atmosphere, resulting in increased high-altitude

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

radiation doses.[31] Typically, changes in the standard flight path do not significantly alter the estimated mean effective dose rate.[32] The cosmic radiation field in the aircraft is relatively uniform; consequently, the exposure of individual passengers and crew is similar.

Abnormalities

Cytogenic studies indicate that some cell damage occurs in astronauts and cosmonauts as a result of cosmic radiation present in the thin atmospheres of their orbiting vehicles.[33] A study of peripheral lymphocytes from seven astronauts demonstrated an elevated incidence of chromosome-type aberrations but not chromatid-type aberrations when comparing blood samples before and after space flights; one astronaut had several multi-chromosomal-type aberrant cells (rogue cells).[34] The frequency of the chromosome-type aberrations was correlated to the estimated dose of cosmic radiation. All 16 astronauts tested within 1 month of long-term space flights (i.e., >3 months) had a higher frequency of chromosome exchanges than their preflight yield.[35] There was a trend of declining exchanges with time after space flight; however, this trend was not present in all astronauts. Studies of 36 cosmonauts demonstrated similar results with an increased incidence of chromosomal aberrations (dicentrics, centric rings) in post-space flight evaluations; this cytogenic damage decreased over 1.5–2 years after the flights, but the values did not return to preflight values.[36] The mean dose of space radiation was 110 mGy. The evidence of chromosomal aberrations in airplane flight personnel is less consistent. A study of 59 female cabin attendants, 31 station ground personnel, and 56 female clerks did not detect a statistically significant difference in the frequency of dicentric chromosomes between the 3 groups.[37] Similarly, the frequency of chromosome translocations in peripheral blood lymphocytes of 83 airline pilots and 50 control personnel did not differ statistically; however, the frequency of translocation in the pilots correlated to flight years ($P = 0.01$) with rate ratios of 1.06 (95% CI: 1.01–1.11) for a 1-year incremental increase in flight and 1.81 (95% CI: 1.16–2.82) for a 10-year incremental increase in flight years.[38] Positive studies included an 8-fold increase in dicentric chromosomes in 18 Concorde pilots (mean effective dose rate, 11–37 mSv/year) compared with 10 controls[39] and statistically increased relative risks of translocations (adjusted OR = 5.1, 95% CI: 1.5–17.3) and gaps/breaks (adjusted OR = 7.8, 95% CI: 2.4–24.9) in 48 male airplane crewmembers working long-haul flights.[40] The control group contained 48 ground staff.

HEALTH SURVEILLANCE

Risk Assessment

There is little direct evidence that exposure to typical natural ionizing radiation doses in the environment (i.e., <100 mSv) produces adverse health effects; however, excess cancer is *assumed* to occur as a result of low-level radiation exposure because a threshold dose for cancer development is not generally accepted for protection purposes.[4] Risk estimates for natural radiation are extrapolated from high-risk groups (e.g., Japanese atomic bomb survivors, workers in nuclear facilities, patients exposed to high radiation doses). The values obtained from these risk estimates depend on several factors including 1) the type of mathematical model (linear, quadratic, linear-quadratic) chosen, 2) the dose rate effectiveness factors used to extrapolate acute dose to chronic exposure, 3) the type of health effect (cancer deaths, cancer incidence, genetic, miscarriages), and 4) the age of the population. The International Commission on Radiological Protection (ICRP) uses an estimate of 0.05 cancer deaths per Sv for the general population. Using the ICRP estimate, the expected annual cancer deaths in a population of 30 million exposed to an annual effective dose equivalent of 2.5 mSv would be 3,750.

Environmental Monitoring

The ICRP recommends setting reference levels for occupational exposure to cosmic radiation within a range of 1–20 mSv, primarily in the 5–10 mSv range, as an effective annual dose rate.[3] The selected reference value represents the upper limit of the dose level with the actual level reduced as low as reasonably achievable given prevailing social and economic factors. The main action to reduce radiation exposure in aviation is the adjustment of flight schedules for the highest-exposure worker by altering flight times and routes (i.e., latitude, altitude). Shielding the aircraft fuselage is not practical because of the added weight necessary to reduce radiation exposure. Several limitations restrict the overall effectiveness of these measures to reduce radiation exposure including increasing the number of workers exposed to radiation (if flight time increases) and increasing the risk of accidents, flight distances, time, and costs due to rerouting.

Other ICRP recommendations for aircraft crews include 1) an educational program to inform the flight crew individually about cosmic radiation, 2) assessment of the radiation dose using a validated computer model, 3) keeping records of the individual and cumulative dose of the crew; these records should be kept

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for the lifetime of the individual, and 4) adjusting the flight roster when appropriate based on selected dose reference level in consultation with the crewmember.[20] For frequent flyers, the Commission recommends self-assessment of the individual's dose and adjustment as needed. Pregnant frequent flyers may also need to adjust their flight exposure based on their assessment of exposure. Frequent flyers (i.e., >500 hours/year) should be managed similarly to aircraft crews. Occasional flyers do not usually require measures to protect them from cosmic radiation.

Medical Screening

The IRCP recommends annual assessment of the effective radiation dose rate for aircraft crewmembers based on validated computer models of individual flight times and routes. Although real-time alert systems are not recommended, the IRCP recommends the occasional use of on-board ambient monitoring to verify dose calculations of cumulative radiation exposure. Aircraft crews undergo routine medical evaluations for reasons other than cosmic radiation exposure; exposure to cosmic radiation does not require any specific additional medical examinations. After a woman becomes pregnant, working conditions should be adjusted to ensure the additional radiation dose to the embryo/fetus during the rest of the pregnancy does not exceed a total dose of 1 mSv.

RADON

PHYSICAL PROPERTIES

Radon is a colorless, odorless, tasteless, nonirritating, chemically inert, noble gas emitted from rocks (e.g., granite) containing uranium; this substance is the heaviest noble gas in the uranium decay series. Radon has an atomic number of 89. Air pressure inside houses is usually lower than outside air pressure; therefore, soil gas containing radon tends to enter dwellings. Most of the natural radiation dose from radon results from the emission of α-particles during the decay of radon to polonium, lead, and bismuth. When discussing radiation exposure, the term "radon" commonly encompasses all radon isotopes and their short-lived decay products produced by the radioactive decay of the uranium and thorium series. Although there are 25 radon isotopes, only 3 of them occur naturally. ^{226}Ra is an intermediate decay product (fifth progeny) of the ^{238}U series; ^{226}Ra decays directly to radon (radon-222, ^{222}Rn). ^{219}Rn (actinon) is a relatively rare, short-lived radon isotope formed from ^{235}U decay. The physical half-life of ^{219}Rn is 4 seconds. Radioactive decay of the ^{232}Th with emission of an α-particle produces ^{220}Rn (thoron); radioactive decay of the ^{238}U series does not result in the formation of ^{220}Rn.

^{222}Rn is the most stable radon isotope with a physical decay half-life of 3.82 days compared with ^{218}Po. Figure 38.3 displays the decay scheme of ^{222}Rn that ultimately produces the stable isotope ^{206}Pb. Radon progeny are decay products of ^{222}Rn outlined in the heavy boxes on Figure 38.3. These progenies emit primarily α-radiation in the following proportion: ^{214}Pb – 52%, ^{214}Bi – 38%, and ^{218}Po – 10%.[41] The diffusion of radon is limited with 90% of radon decaying before traveling 5 m in air, 5 cm in water, or 2 m in soil.[42] The immediate progeny of radon are positively charged, radioactive isotopes of solid elements that rapidly form particles with water molecules. These particles are small (i.e., ~0.001 μm), highly mobile, and attach to aerosol particles that are ubiquitous in air.[43] The progeny of ^{222}Rn settle on the pulmonary surface after attaching to aerosol particulates.

EXPOSURE

The radioactive decay of the ^{238}U series causes the slow, continuous formation of radioactive gaseous (radon) that subsequently produces α-emitting, reactive solids (termed radon progeny, radon progeny). Radon is a relatively inert noble gas that emanates primarily from soil and, to a lesser extent, from water. The adverse health effects of radon result from its decay products (radon progeny). Both radon and its progeny emit α- and β-particles as well as γ-radiation; however, most toxicity ensues from α-radiation emitted from airborne particles (dust, water droplets) containing radon progeny rather than from the original gaseous radon. Deposition of these radon progeny in the lungs results in irradiation of the pulmonary lining with α-radiation and an increased lung cancer risk.

Potential occupational sources for ^{222}Rn include underground mines, oil or natural gas extraction, and cement or phosphate production.[45] Calibration of measuring instruments is the only commercial application of radon in the United States; radon is no longer used in radiology or cancer radiotherapy.

Sources

Radon is a ubiquitous, radioactive gas in soils and, to a lesser extent, some building materials that results

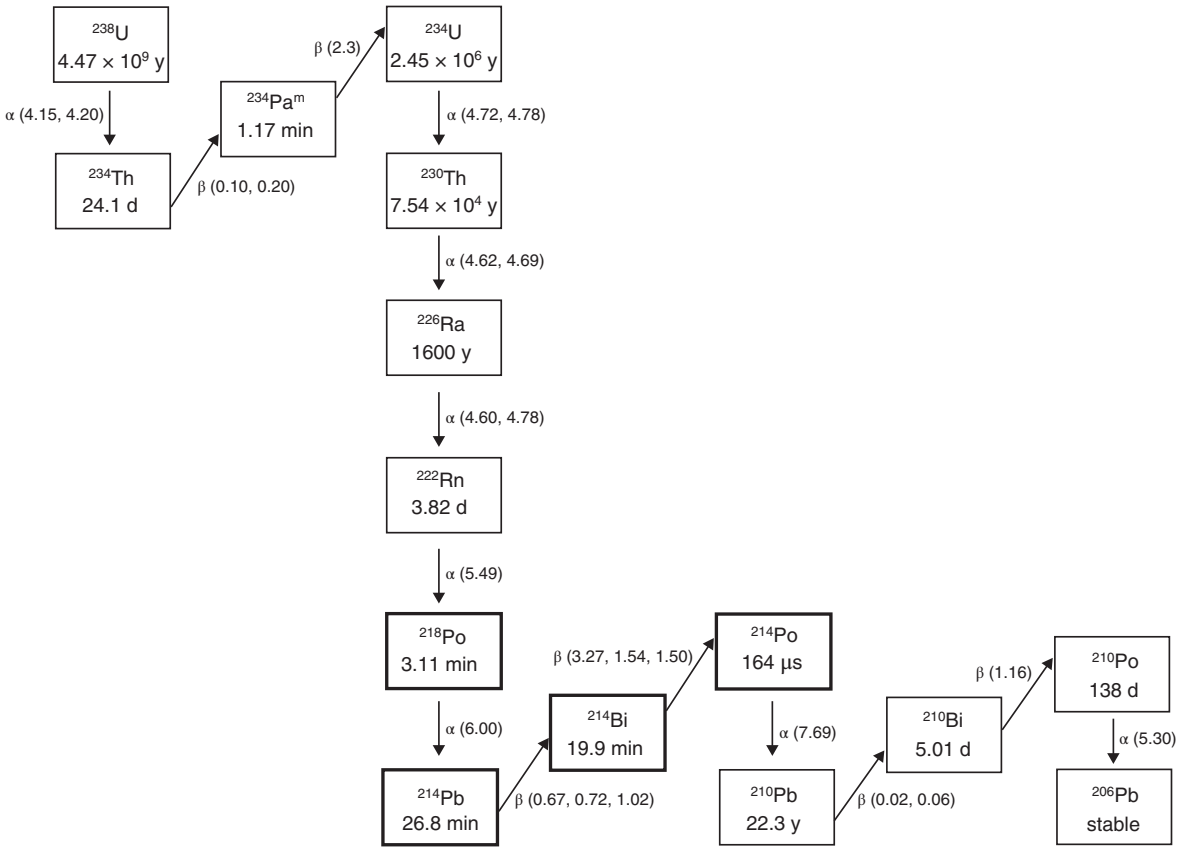

FIGURE 38.3. Principal decay scheme for ^{238}U to stable ^{206}Pb including radon and radon progeny (bold outline) with associated half-lives. *Abbreviations:* α = alpha particle, β = beta particle, d = days, min = minutes, µsec = microseconds, y = years. (Samet).[44]

from the decay of the ^{238}U series and specifically the decay of ^{226}Ra following the emission of an α-particle. ^{222}Rn contributes ~50–70% of the absorbed radiation dose from the natural environment,[46] whereas overall radon exposure represents 37% of the total effective dose of ionizing radiation in the general population compared with 48% from medical procedures and 15% from background cosmic and terrestrial radiation.[47] The quantity of ^{226}Ra in earth materials is not a direct determinate of the amount of ^{222}Rn present in the air; however, the content of ^{226}Ra in the ^{238}U series is an indicator of the potential for radon production in the soil and bedrock. Although the amount of ^{220}Rn from the ^{232}Th series and ^{222}Rn from the ^{238}U series produced in the environment is similar, the short physical half-life (56 seconds) and poor aerosolizing properties of ^{220}Rn limit environmental concentrations and adverse health effects of ^{220}Rn. Typically, the average airborne ^{220}Rn concentration is 5-fold lower than ^{222}Rn; uranium mines do not usually contain clinically significant amounts of ^{220}Rn.[42] US Mine Health and Safety Administration data indicate uranium and vanadium mines contain the highest median potential alpha energy concentrations (PAECs) as measured in WL units.[48] Potential radon exposure in the occupational setting includes phosphate production, tourist caves, and waterworks. Phosphate rock commonly contains uranium, radium, and thorium impurities with uranium concentrations in US deposits ranging from 10–400 ppm.[49]

High natural background radon concentrations occur in several areas around the world including Brazil (Guarapari, in the Atlantic coast state of Espirito Santo; Pocos de Caldas, Araza, and Tapira in the Minas Gerais State), China (Yangjiang County, Gaungdong Province in south China), India (Kerala region in southwest India), and Iran (Ramsar in coastal city in northern Iran).[50] A typical classification system for separating radon exposure based on an annual effective dose involves 1) *low*, ≤5 mSv, 2) *medium*, 5–20 mSv, 3) *high*, 20–50 mSv, and 4) *very high*, >50 mSv.[51] The upper bound of the low category represents twice the mean background natural radiation, whereas the high category begins at the upper guideline for occupational exposure. Breathing air containing 300 Bq/m^3 for 1 year

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. corresponds to an effective annual radiation dose of 5 mSv. The Committee on the Biological Effects of Ionizing Radiation (BEIR VII) considers cumulative linear energy transfer (LET) radiation below 100 mSv as a low dose, whereas medium- and high-level categories are not typically relevant to environmental studies.[52]

Soil adjacent to a house is the primary radon source rather than drinking water or building materials.[53] The entry of radon into structures is highly variable depending on primarily 1) a constant input rate (~80% of the total input in calm weather) from the diffusion of ^{222}Rn through floors and walls, and 2) a variable rate resulting from the indoor-soil pressure differentials.[54] The amount of radon emanating from building materials depends on the amount of ^{226}Ra present in the material and the radon fraction released from the material. In a study of building materials and radon, the emanating radon fraction from building materials averaged 4% of the total radon dose with a range of 0.3–12%.[53] In poorly ventilated masonry buildings, the percent of the total dose of radon contributed by the cement blocks ranged up to 20%.[55] The radon in soil gas diffuses through rocks and soil into subsurface air pockets with radon concentrations exhibiting a diurnal cycle. Minimum levels occurred at sunset, whereas maximum concentrations arose at sunrise.[56] Radon enters the house through cracks and pores caused by the pressure differential between the soil and the house. The ventilation rate controls radon transport within the structure.[57]

Concentrations

The amount of radon diffusing from soil into homes depends on the following factors: porosity of the soil, occupant activities, tightness of the house construction, local ^{226}Ra concentration, pressure differential between the inside and outside of the house, humidity, wind conditions, and the home temperature compared with the soil. Typically, the amount of indoor radon is an order of magnitude greater than outdoor radon concentrations as a result of differences in ventilation and dispersion.[5] In well-ventilated houses (2 air exchanges/hour), the level of radon decay products is ~30% of the radon concentration in contrast to ~50% without significant ventilation.[43] Reducing the ventilation rate from 1 air exchange/hour to 0.5 air exchanges/hour increases the annual effective radon dose equivalent to 2.83 mSv from 1 mSv.[58] The construction of tight, energy-efficient buildings with increased weather stripping and subsequent reduced ventilation can increase indoor radon levels by a factor of ~50%.[59] However, the differential in radon levels between floors in the same home is small compared with the differential between the same floor in different homes.[53,60] The main driving force for the migration of radon from cellars to the upper floors of a home is called the stacking effect.[61] This effect results from the development of a pressure differential across vertical walls separating air masses with different temperatures. Heating a structure and opening windows to decrease the indoor–outdoor pressure differential strongly influence the diurnal cycle of radon levels.

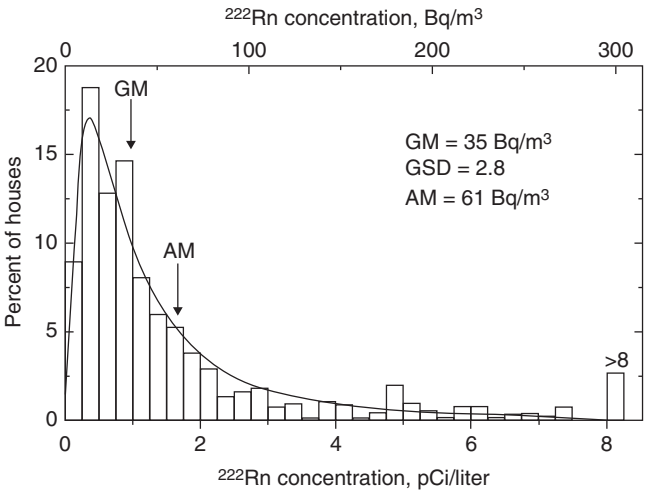

FIGURE 38.4. The probability distribution of ^{222}Rn in 552 US homes with the associated geometric mean (GM), geometric standard deviation (GSD), and arithmetic mean (AM). (Redrawn from Nero et al.).[62]

The radon level in homes follows a log-normal pattern with most homes containing relatively low radon levels and a small number with moderate-to-high radon levels.[62] Radon levels in homes in the United Kingdom and the United States vary by >2 orders of magnitude; radon exposure at work and home is usually similar unless the work involves underground exposures.[53,63] Figure 38.4 demonstrates the probability distribution of radon in a convenience sample of 552 US homes, where the geometric and arithmetic means were 35 ± 2.8 Bq/m^3 and 61 Bq/m^3, respectively. In a UK study by the National Radiological Protection Board, the mean indoor and outdoor radon concentrations were 22.3 Bq/m^3 and 3.5 Bq/m^3, respectively.[64] A collaborative analysis of radon data from 13 case-control studies of residential radon and lung cancer demonstrated a mean radon concentration of 104 Bq/m^3 in 7,148 homes of lung cancer patients compared with 97 Bq/m^3 in 14,208 control homes.[65] The estimated radon concentration for each individual was calculated as a time-weighted average of the measured radon concentrations in all the homes occupied over the past

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. 5–34 years (based on a latent period of 5 years) with weights proportional to the length of time the individual had lived in each home. Radon concentrations are not constant within a building. Typically, radon concentrations are highest in basements with concentrations declining as the elevation increases from ground level.

A study of US homes indicated that the average radon concentration was 55.5 Bq/m^3 (1.5 pCi/L), with 1–3% of the homes demonstrating levels of >296 Bq/m^3 (>8 pCi/L).[63] This study demonstrated a geometric mean of 33.3–103.6 Bq/m^3 (0.9 ± 2.8 pCi/L). In the Reading Prong area of eastern Pennsylvania, the highest indoor radon concentration was 74,000–111,000 Bq/m^3 (2,000–3,000 pCi/L).[66] The highest average radon level in a UK study occurred in Devon and Cornwall, with ~5% of the homes exceeding 400 Bq/m^3. In California, only 0.8% of 310 homes surveyed for radon exceeded the recommended radon limit of 148 Bq/m^3 (4 pCi/L), whereas the radon level did not exceed 740 Bq/m^3 (20 pCi/L) in any house.[67] In an analysis of two national Swedish studies of radon and cancer, the mean radon concentrations in these dwellings were 113 Bq/m^3 in 1990 and 90 Bq/m^3 in 2008, with 8% of the studied population living in houses with >200 Bq/m^3.[68]

ENVIRONMENTAL FATE

Radon acts as a carrier of α-particle decay energy from the ground to the biosphere. In the atmosphere, aerosols absorb the short-lived progeny (^{214}Bi, ^{214}Pb, ^{214,218}Po). The direct source of radon and its decay products is the presence of ^{226}Ra in building materials, soils, water, and natural gas. The 3.82-day half-life of ^{222}Rn allows the diffusion of this noble gas into air or water over substantial distances.

Soil

The crystalline structure in radioactive rocks (e.g., granite, shale, phosphate) tightly binds the radon released by the radioactive decay of ^{238}U and ^{226}Ra. Heavily fractured rocks containing uranium allow radon to be released into the atmosphere. The southwest portion of England contains the highest radon concentration in that country, even though the risk of lung cancer in that area is comparatively low.[69] Most soils including granite contain 1–4 ppm uranium, whereas phosphate-rock formations in Florida comprise up to 120 ppm uranium.[70] In the United States, the Reading Prong area of Pennsylvania, New York, and New Jersey also possesses unusually high uranium concentrations. Underground uranium mines possess the highest radon risk from exposure to radon progeny, silica dust, diesel fumes, and cigarette smoke. Significant radon concentrations may also occur in iron ore, fluorspar (fluorite), gold, lead, potash, tin, and zinc mines.

Water

Radon levels are relatively low in surface water compared with groundwater; the radon concentrations in groundwater range from 200–600 pCi/L (~7–22 Bq/L). Radon diffuses through groundwater with the mechanical flow of the water. Because the water solubility of radon is low and the half-life is short, most radon decay occurs before the release of radon gas from groundwater. Radon concentrations in large aquifers average ~240 pCi (8.8 Bq) ^{222}Rn/L water; however, water in private wells may demonstrate radon concentrations two to three times higher.[71] In a German study of 582 public drinking-water samples, the radiation dose from ^{222}Rn ranged from <1.3–1,800 Bq/L, with a median of 7.3 Bq/L and a 95th% of 140 Bq/L.[72] Hence, groundwater is not a significant radon source (i.e., usually <10% of the annual effective dose of radiation) compared with radon release from soil, unless the radon concentration in well water is ≥300 Bq/L water.[73] Radon gas can transfer from water to air during water treatment. The geometric mean of the annual average airborne radon concentration of workers in water treatment plants was 3.4 pCi/L (126 Bq/m^3) with a maximum of 133 pCi/L (4,921 Bq/m^3).[74] Radium concentrations in the oceans do not contribute significantly to the radon burden in air because the radium concentrations in groundwater are three to four orders of magnitude less than soil concentrations.[42]

Air

Radon release from ^{226}Ra in soil is the dominant radon source in the atmosphere.[57] The rate of emanation is highly variable depending on several factors including temperature, humidity, barometric pressure, wind, soil moisture, and soil composition. Although most radon in groundwater decays before reaching the surface, the emanation of radon from groundwater is the second-largest radon source. An estimated 20% of the radon in the tailings from uranium and phosphate mines is released into the atmosphere; emanation rates of radon near these tailings range up to 1,000 pCi (37 Bq)/m^2/second. Negligible radon amounts reach the stratosphere. People working in caves (e.g., park service employees) may receive radon doses similar to underground miners; however, the casual visitor does not receive significant radon doses.[75]

DOSE EFFECT

Estimation of the delivered dose of radon and radon progeny requires very complex mathematical models with the dose depending on multiple assumptions including time spent indoors/outdoors, aerosol kinetics and concentrations, size and distribution of particles, house ventilation, and the respiratory rate. The lungs exhale most of the radon reaching the tracheobronchial tree; hence, the short-lived decay products of radon (radon progeny, formerly "radon daughters") are the most clinically important component of the radiation dose following inhalation of radon.[76] Longer-lived radon progeny (e.g., ^{210}Pb, ^{210}Po) contribute minimal radiation doses to lung tissue because of the likelihood these progenies are eliminated by cellular or mucociliary transport prior to radioactive decay. Figure 38.5 displays the short- and long-lived radon progeny with their associated half-lives.

In epidemiology studies, the benchmarks for radon exposure are year-long measurements of contemporary radon concentrations with α-track detectors; temporal fluctuations result from differences in climate, environment, lifestyle, and structure of the homes. The estimated mean radon levels in US homes range from ~1–1.5 pCi/L (~37–56 Bq/m^3); this value correlates to ~20 WLM over a lifetime of 70 years.[77] An estimated 8.5 million US homes exceed the US action level of 148 Bq/m^3 (4 pCi/L) based primarily on short-term testing (i.e., ~98%).[78] In a study of 98 Minnesota homes from 1983–2000, the median radon concentration was 120 Bq/m^3.[79] Although median radon concentration within each house varied little year-to-year with no consistent temporal trends, annual radon doses varied by 3–110% (median = 26%) between individual sites. Climate, wind exposure, radon concentration, and building attributes (heat/ventilation systems, house structure) contributed to the variation. The daily radon dose derived from drinking water averages 3.7–22.2 Bq ^{222}Rn; these values represent ~2% of the daily US indoor dose. For the average individual in the United Kingdom, the estimated annual effective dose equivalent from radon decay products is ~0.8 mSv within a range of 0.1–100 mSv.[5]

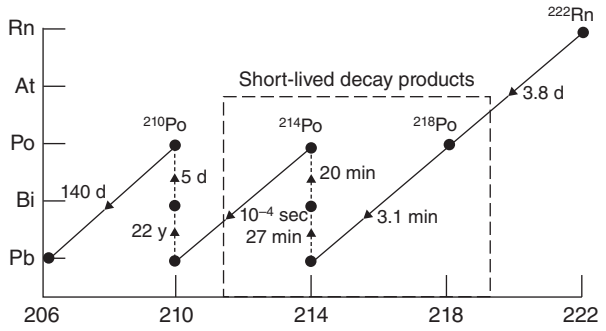

FIGURE 38.5. Short-lived decay products of ^{222}Rn to ^{210}Pb and subsequent conversion to stable ^{206}Pb. ^{214}Po and ^{214}Bi contribute negligible radiation doses because of their very short half-lives. (Kendall and Smith).[76]

Depending on assumptions about equilibrium, an annual radon dose of 1.3 pCi/L (~48 Bq/m^3) correlates to a pulmonary dose of 3.1–4.6 rem (31–46 mSv).[80] Using the ICRP weighting factors for radiation quality and tissue sensitivity, the NCRP action level of 200 Bq ^{222}Rn/m^3 air corresponds to an annual effective dose equivalent of 10 mSv.[64] The ICRP concluded that average annual radon concentrations of 200 Bq/m^3 and cumulative occupational concentrations of ~50 working level months (WLMs) are associated with a significantly increased lung cancer risk.[81] The radon dose for children may be higher than for adults because of differences in lung anatomy and minute ventilation rates.

TOXICOKINETICS

Absorption

Inhalation is the primary route of exposure to radon and its progeny. Radon is an inert gas that diffuses across alveolar membranes; however, the lungs exhale most inhaled radon before decay and emission of α-particles.[82] Radon progeny (daughters) attach to the surface of aerosol particles before depositing on the lining of the respiratory tract through impaction, diffusion, and sedimentation. Most deposition occurs in the tracheobronchial portion of the lung with the first bifurcation of the bronchi being the primary site.[57] Systemic radon absorption is minimal; therefore, sites other than the lung receive little radiation with the exception of the stomach and skin, depending on the amount of contact with radon progeny.[83]

Most radon absorption following ingestion of water occurs rapidly in the stomach and small intestine with ~1–3% crossing the epithelial lining in the large intestine.[84,85] Absorption is more complex for radon decay products than radon, occurring primarily in the small intestines with several absorption phases involving minutes to several hours.[86] Although data on the dermal absorption of radon are limited, experimental studies suggest dermal radon absorption is small; however, radon decay products may expose the skin to substantial α-radiation.[57]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Distribution

The distribution of radon following inhalation depends on the physical properties of radon and its progeny. Although the radioactive decay of radon progeny is relatively short-lived, radon progeny contribute most of the radiation dose to the respiratory tract following radon exposures; these progeny are sufficiently long-lived to create complex toxicokinetic processes that govern transport and distribution, particularly because radon progenies are inhaled from the natural environment along with radon. The mucociliary mechanism transports radon particles to the trachea and the gastrointestinal tract. Radon concentrations in body organs can reach 30–40% of the systemically absorbed radon dose following chronic exposure; however, radon absorption is much lower from the gastrointestinal tract than the lungs.[87] The stomach wall receives the vast majority (i.e., ~95%) of the ingested radon dose depending on radon loss from the stomach; the estimated effective dose for 1 Bq radon in drinking water is 1×10^{-5} assuming a half-time of 20 minutes in the stomach.[88]

Elimination

Radon is an inert gas that does not interact chemically with cell constituents. The lungs eliminate most inhaled radon before significant radioactive decay occurs.[57] The biological half-lives of radon progeny in the lung range from ~6–60 hours, while the half-life in the upper airway near the carina is ~0.16–4.8 hours.[89,90] The urinary excretion of ^{210}Pb in uranium miners after cessation of radon exposure suggests the slow release of radon progeny from bone.[91] Experimental studies in humans indicate the lungs exhale >90% of an absorbed dose of radon from water within 100 minutes; ~1% of the absorbed dose remained in the body after 10 hours.[92] Except for slight differences in tissue solubility, ^{133}Xe and ^{222}Rn share similar kinetics; ^{133}Xe elimination studies are consistent with the rapid excretion of radon from the body. No radioactivity remained in the bodies of 5 volunteers exceeding 0.75 μCi 24 hours after the ingestion of a few mCi of ^{133}Xe.[93]

Maternal-Fetal Kinetics

Rodent studies suggest ^{222}Rn easily crosses the placenta to produce similar maternal and fetal radon concentrations, whereas all short-lived progeny do not diffuse through the placenta.[94]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Radon does not accumulate in the respiratory tract; consequently, radon toxicity results primarily from inhalation of α-radiation during the radioactive decay of radon progeny ^{218}Po, ^{214}Bi via β-, and γ-decay, and the essentially instantaneous decay of ^{214}Po to ^{210}Pb. The β- and γ-radiation from radon progeny is small compared with the α-radiation from radon progeny. The dose of α-radiation is much higher in the upper than lower bronchial epithelium; consequently, bronchogenic carcinoma is a common sequelae of radon exposure.[95] The ionizing radiation from α-particles penetrates bronchial epithelium to a depth of ~70 μm (5 cell diameters), resulting in DNA breakage, repair mistakes (deletion, insertion, rearrangement), chromosomal changes, gene mutations, genetic instability, apoptosis, dysfunctional regulatory genes, and ultimately malignancy.[96] Radon releases high linear energy transfer (LET) particles that produce indirect intranuclear damage via free radical formation. These reactive oxygen species alter p53 stability and damage individual DNA bases leading to point mutations and mispairing during DNA replication. Cigarette smoke strongly enhances the carcinogenic effects of radon in a supra-additive but sub-multiplicative relationship.[97] Both tobacco smoke and ionizing radiation induce oxidative stress via the formation of reactive oxygen intermediates. Subsequent base DNA damage, and potentially base excision repair errors, altered gene expression, and genomic instability.

Radon exposure is not associated with a specific histological subtype of lung cancer, with squamous cell carcinoma and adenocarcinoma being the most common subtypes in the East German study of 240 miners from the Wismut cohort; almost all miners in this group were smokers.[98] Early reports suggested small cell bronchogenic cancers accounted for most radon-induced lung cancers in miners exposed to radon progeny.[99] Subsequent studies of uranium miners indicate the incidence of small cell bronchogenic cancer may exceed the incidence in the general population; however, all types of lung cancer occur in uranium miners including squamous (epidermoid) carcinoma, small (oat) cell carcinoma, large cell carcinoma, adenocarcinoma, carcinoid tumors, and bronchial gland carcinomas.[60] Frequently, the tumor site is the upper airway near the carina, although the exact original location is often difficult to determine when the lung tumor is advanced. The sequencing of DNA exons of the p53 tumor suppressor gene in lung cancer from uranium miners suggests the lung cancer mutational spectrum

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. of radon-induced cancer differs from the direct DNA sequencing of lung tumors associated with smoking.[100]

CLINICAL RESPONSE

Radon exposure is the second-most common cause of lung cancer in the United States behind tobacco smoking, whereas radon is the most common cause of lung cancer in never-smokers.[101] The US EPA estimates 5,000–20,000 annual cases of lung cancer occur in the United States from exposure to radon progeny whereas other reviews suggest the number of new lung cancer cases ranges from 3,000–33,000 cases.[102,103] The attributable risk of radon-induced lung cancer mortality varies between countries depending on radon distribution, exposure, and treatment. The estimated population attributable fraction for lung cancer induced by residential radon exposure was 8.3% in Switzerland and 5.0% in Germany.[104] The National Radiological Protection Board estimates ~1,500 UK deaths occur from radon exposure;[105] however, the risk of developing lung cancer from radon exposure is at least an order of magnitude below that of chronic smoking.[106]

Environmental Exposure

There is no evidence that radon exposure increases nonrespiratory mortality based on Cox proportional hazards regression models using ecological data from the American Cancer Society Cancer Prevention Study II on radon exposure (mean county-level residential radon concentration = 53.5 ± 38.0 Bq/m^3).[107]

Occupational Exposure

Diffuse interstitial fibrosis occurs in the lungs of some uranium miners; however, multiple potential etiologies for these diseases exist in uranium mines including silica, diesel exhaust, and tobacco smoke.[108] In a cohort of 58,690 German uranium miners followed from 1946–2008, 2,336 deaths were attributed to nonmalignant respiratory diseases including 715 deaths from chronic obstructive pulmonary disease (COPD) and 975 deaths from silicosis or other pneumoconiosis.[109] The relative risk of death did not correlate to cumulative radon doses. The mean estimated cumulative radon exposure was 280 WLM with a median of 33 WLM and a maximum of 3,224 WLM. Compared with the US population, standardized mortality ratios (SMRs) for interstitial pulmonary fibrosis were highly elevated in white (SMR = 3.95, 95% CI: 2.41–6.11, $n = 20$) and American Indian (SMR = 8.70, 95% CI: 4.17–16.0, $n = 10$) miners.[110] The SMR for pulmonary fibrosis in never-smokers was 4.1 (95% CI: 1.7–8.5). Pulmonary fibrosis is a common result of exposure to several types of agents (smoking, γ-radiation, silicosis, diesel exhaust). Misclassification of pulmonary disease and the cause of death also remains problematic because of the difficulty in differentiating pulmonary fibrosis from obstructive lung diseases and pneumoconiosis. The exact contribution of radon progeny to the development of diffuse pulmonary fibrosis remains unclear.

Carcinogenesis

The US National Toxicology Program (NTP) lists ionizing radiation including ^{220}Rn and ^{222}Rn as known to be a human carcinogen; the International Agency for Research on Cancer (IARC) classifies ^{222}Rn and its decay products as Group 1 (human) carcinogens based on increased lung cancer in uranium miners. Although most studies of uranium workers have not detected elevated risks of leukemia,[111] analysis of leukemia rates in Czech uranium miners provided some evidence for an association of cumulative radon exposure with an increased leukemia risk. However, coexposure to γ-radiation and other radionuclides confounded the results. Most case-control studies of children and adults have not detected an increased risk associated with residential radon exposure. Currently, there is no convincing evidence of nonpulmonary solid tumors associated with exposure to radon or radon progeny.

Residential

The results of ecological and observational studies associating documented radon exposure in homes with an increased lung cancer incidence are inconsistent, potentially resulting from potential recall bias, exposure misclassification, and wide variation in radon concentrations in homes and between geological areas, confounding from differences in smoking rates, and limited statistical power.[112] Most studies suggest a positive association; however, only a few of these studies demonstrated a statistically significant increase in lung cancer risk.[113,114] More recent analyses of pooled case-control study data indicate a consistent, relatively small increased risk of lung cancer with long-term radon exposure; the health implications of this excess risk are substantial because of the size of the population exposed to radon.

Lung Cancer

A meta-analysis of 17 case-control studies demonstrated a positive dose-response relationship between residential radon exposure and lung cancer risks.[115] The pooled odds ratio ranged from 1.07 (95% CI: 1.04–1.11) for exposure to 50 Bq/m^3 to 1.24 (95% CI: 1.11–1.38) at 150 Bq/m^3 and 1.43 (95% CI: 1.19–1.72) at 250 Bq/m^3. Pooling studies restricted to women and excluding men increased the estimated odds ratio. In a prospective Danish cohort of 52,692 persons exposed to low to medium radon levels (median = 35.8 Bq/m^3) followed for ~10 years, the adjusted incidence rate ratio (IRR) for lung cancer was 1.04 (95% CI: 0.69–1.56) for all participants exposed to 100 Bq/m^3.[116] For nonsmokers, the IRR was 1.67 (95% CI: 0.69–4.04) with a dose-response trend. None of the associations were statistically significant. In a study of pooled data from 7 North American case-control residential studies involving 3,662 lung cancer cases and 4,966 controls, the estimated OR after radon exposure at a concentration of 100 Bq/m^3 5–30 years before the index date was 1.11 (95% CI: 1.00–1.28).[117] The estimate was compatible with extrapolation of the miner data to the residential radon concentrations determined by long-term α-track detectors; the downward extrapolated estimate was 1.12 (95% CI: 1.02–1.25). A Swedish case-control study of 586 women and 774 men with lung cancer demonstrated cancer risks consistent with the estimates based on data in miners.[118] The relative risk of residential exposure to radon concentrations of >10.8 pCi/L (>400 Bq/m^3) was 1.8 (95% CI: 1.1–2.9).

A population-based case-control study of 292 cases of small cell and nonsmall cell lung cancers in Swedish women demonstrated a statistically significant increased risk (RR = 2.2, 95% CI: 1.2–4.0) for women exposed to radon concentrations of >150 Bq/L air.[119] Radon exposure was based on the measurement of samples and locations near areas commonly associated with radon exposure and the measurement of samples from 10% of the residences rather than direct radon measurements. Smoking was not a major confounder in this study; however, a detailed smoking history was not available for the study participants. Another Swedish study of pathologically mixed lung cancer cases in 210 women with average radon concentrations of >150 Bq/m^3 (4 pCi/L) revealed a statistically marginally increased RR of 1.7 (95% CI: 1.0–2.9).[120] A systematic review of residential radon exposure and small cell lung cancer suggested lung cancer risks following radon exposure are greater for small cell lung cancer than nonsmall cell lung cancer;[121] a hospital-based case-control study also suggested the presence of *GSTT1* and *GSTM1* deletions increases susceptibility to lung cancer following radon exposure.[122]

Nonpulmonary Cancer

Ecological studies on cancer incidence and radon in drinking water have not clearly demonstrated an association between nonpulmonary tumors and residential radon exposure;[123] however, methodological limitations (limited sample size, exposure assessment, confounding) restrict conclusions regarding causation and dose effect at naturally occurring radon concentrations.[124] An ecological study of the incidence of monocytic leukemia, myeloid leukemia, and other childhood cancers suggested a positive association between regional estimates of radon exposure and these cancers;[125,126] however, a French study of acute childhood leukemia involving 2,763 cases and 30,000 population controls did not detect an increased acute leukemia risk with radon exposure, irrespective of the acute leukemia subtype or age group.[127]

Although a meta-analysis of 6 case-control studies on childhood leukemia reported an elevated overall odds ratio of 1.37 (95% CI: 1.02–1.82) comparing the highest and lowest residential radon exposures,[123] the evidence for an increased risk of childhood cancers (i.e., leukemia, lymphoma, central nervous system) from residential radon exposure is weak and inconsistent, primarily resulting from the uncertainty in the radon dose estimates. Residential radon exposures in Norway and Switzerland are relatively high compared with other European countries. A cohort study based on Norwegian population registers containing 712,674 children <16 years of age was followed from 1967–2009; the study identified 437 cases of childhood leukemia along with 427 cases of central nervous system cancers.[128] The geo-coded radon exposures did not detect significant differences in geometric mean radon concentration between leukemia cases (89.1 Bq/m^3), CNS cancers (100.2 Bq/m^3), and the overall cohort (91 Bq/m^3). After adjustment for confounders, the hazard ratio for childhood leukemia and estimated radon exposure was not significant, whereas the hazard ratio for childhood CNS cancers was borderline significant (17% increase/100 Bq/m^3) following exposure before 5 years of age. The association was not significant for CNS cancer when comparing high (>200 Bq/m^3), medium (100–199 Bq/m^3), and low (<100 Bq/m^3) estimated radon exposures. Similarly, a prospective, census-based cohort study of Swiss children of <16 years of age did not detect elevated adjusted hazard ratios for overall childhood cancers (0.93, 95% CI: 0.74–1.16), all childhood leukemias (0.95, 95% CI: 0.63–1.43), or childhood CNS tumors (1.05, 95% CI: 0.68–1.61) when comparing children with estimated radon exposure below the median (<77.7 Bq/m^3) and ≥90% (≥139.9 Bq/m^3).[129] A study of childhood

lymphoma using the Texas Cancer Registry ($n = 2{,}147$), US Census data, and the Texas Indoor Radon Survey did not demonstrate evidence of increased adjusted incidence rate ratios of overall lymphoma or lymphoma subtypes (Hodgkin, Non-Hodgkin, Burkitt) and estimated residential radon exposures with the exception of diffuse large B cell lymphoma (aIRR = 1.73, 95% CI: 1.03–2.91; $n = 315$).[130] The adjusted incidence of the latter lymphoma subtype did not display a dose-response relationship with estimated residential radon exposure.

Workplace

Lung Cancer

The lung is the primary target organ of radon exposure with excess lung cancer risks known in underground miners from the Erz Mountains in Bohemia and Saxony since the 16th century.[131] The tracheobronchial region of the lung absorbs radiation doses at least an order of magnitude greater than other organs in the body. Epidemiology studies of underground uranium,[132] hard-rock,[133] iron,[134] and niobium[135] miners associated exposure to radon progeny with increased risks of lung cancer; animal studies support this association.[136] The minimum latency period for radon-induced lung cancer in these studies is ~10 years,[57] whereas the usual latency period averages 20–30 years. Several factors (e.g., older age at the time of exposure, high radon doses, heavy smoking) may reduce the length of the latency period.[95] Some conditions (e.g., dusty conditions and diesel exhaust) that contribute to the development of lung cancer are not usually present in the home environment. In the East German Wismut cohort of 59,001 former male employees, the highest risks occurred in the youngest age group (<55 years of age) 15–24 years after exposure; duration of exposure did not modify the relative risk.[137] The highest exposures were associated with a strong inverse exposure-rate effect, whereas this effect was not observed in workers with cumulative exposures below 100 WLM.

Nonpulmonary Cancer

Epidemiological studies of underground miners clearly indicate an increase in the risk of lung cancer from exposure to radon decay products; however, there is little evidence of an increased risk of other diseases.[102] Generally, the radiation dose received by the bone marrow is at least 30–40 times below pulmonary levels.[138] Some mortality studies suggest a positive correlation between radon exposure and leukemia, primarily acute myelogenous leukemia.[139] Studies of Czechoslovakian and Canadian uranium miners revealed no evidence of cancers other than lung cancer in miners exposed to radon concentrations much higher than residential exposures.[140,141] Similarly, a follow-up study (mean duration ~30 years) of a French cohort of uranium miners detected an increased risk of lung cancer mortality (SMR = 1.43, 95% CI: 1.22–1.68; $n = 159$); however, there was no increased risk of leukemia, multiple myeloma, pancreatic cancer, or stomach cancer.[142] The average cumulative exposure was 36.6 working level months (WLM). The presence of confounders of radon exposure (mostly high-LET) and leukemia in uranium miners includes the presence of external γ-radiation (mostly low-LET) and other radionuclides from the ^{238}U series. Examination of data from the East German Wismut Uranium miner cohort through 2013 demonstrated a positive, but statistically non-significant dose-response for nonchronic lymphocytic leukemia mortality (non-CLL, $n = 120$) in the low-LET radiation exposure group with an ERR/Gy = 2.18, 95% CI: −0.41 to 6.37).[143] The ERR/Gy for non-CLL in the high-LET radiation exposure group was 16.65 (95% CI: −1.13 to 46.75). A statistically significant excess occurred for the subgroup of myeloid leukemia (ERR/Gy = 26.02, 95% CI: 2.55–68.99; $n = 99$) in the high-LET radiation exposure group, presumably mostly radon progeny. Leukemia mortality did not demonstrate a dose-response relationship to occupational radon dose in the Wismut cohort.[144] The association of radon with kidney cancer is weak. An increased risk of kidney cancer death (SMR = 2.0, 95% CI: 1.22–3.09; $n = 20$) was observed in this cohort; however, this increased risk was not associated with cumulative radon exposure. In the Czech uranium minor study, the relative risk of the incidence of kidney cancer was not significantly elevated (RR = 1.13, 95% CI: 0.62–2.04; $n = 66$) comparing cumulative lifetime radon exposure of the upper 10% (180 WLM) with the lower 10% (3 WLM).[145] A pooled analysis of 11 uranium miner studies by the BEIR VI Committee did not demonstrate excess cancer risks at sites other than the lung.[102]

DOSIMETRY

Units

Measurements of cumulative radon exposures in mines are typically expressed as working level months (WLM), which assumes 170 working exposure hours/month. In homes, the conversion factor is 1 WL = 200 pCi/L, assuming the equilibrium factor is 0.5. The conversion of pCi/L to Bq/m^3 is independent of the equilibrium

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

factor; therefore, 1 pCi/L = 37 Bq/m^3. Thoron (^{220}Rn) does not typically contribute to radon radiation unless the thoron sources are close to the surface or part of the house construction because the half-life of 54.5 seconds limits the underground diffusion of thoron gas. In contrast, ^{222}Rn can diffuse into homes from several meters away from the structure.

History

In early uranium mining operations, when mines had little ventilation and radon gas was in near equilibrium with its progeny, the safe working level (concentration) of radon gas was estimated at 100 Bq/m^3. Recognizing that radon progeny, rather than radon itself, accounted for most of the lung radiation dose, the safe working level was redefined in terms of radioactive energy per air volume to avoid measuring the activities of all progeny separately. This new "working level" (WL) was defined as the concentration of radon progeny at equilibrium (i.e., no progeny loss due to ventilation) assuming the parent radon 1 L of air releases 1.3×10^5 MeV (2.08×10^5 J/m^3) of α-energy during complete decay. Converting radon gas concentrations to the modern WL requires the use of equilibrium factors to account for equilibrium between parent radon and radon progeny (daughters) due to variations in ventilation.

The working level (WL) is a combination of radon progeny in 1 L of air that releases 1.3×10^5 MeV (2.08×10^5 J/m^3) of α-energy during decay. Converting radon gas concentrations to WL requires the use of equilibrium factors to account for the equilibrium between parent radon and radon progeny (daughters). In modern mines, the concentrations of radon progeny are usually expressed in WL with a conversion factor of 1 WL = 300 pCi/L assuming an equilibrium factor of 0.33. Some organizations (e.g., US Environmental Protection Agency) use an equilibrium factor of 0.5 for mine data, resulting in 1 WL = 7,480 Bq/m^3. Table 38.7 displays the conversion factors for converting the traditional units of radon concentration in air (pCi/L) to radon progeny (WL) and duration of exposure to radon progeny over time (WLM/year) as expressed in nominal months (1 nominal month = 170 hours).

TABLE 38.7. Conversion of radon exposure into traditional units of activity, energy, and exposure.

Radon Air Concentration (Activity, pCi/L)	Radon Progeny Air Concentration (Energy, WL)	Progeny Concentration over Time (Full-Time Exposure, WLM/Year)
Indoors		
1	0.005	0.25
4	0.02	1
200	1	50

Mines		
4	0.013	0.16
300	1	12

Abbreviations: pCi = picocurie (2.2 radioactive decays/minute); WL = working level; WLM = working level month.

Radioactivity

The picocurie per liter (pCi/L) is the unit of measure for radon concentrations in the air, whereas the working level unit describes the potential α-decay energy concentration of the combined radon progeny. The pCi represents ~2.2 decays per minute with typical indoor radon concentrations typically ranging from 1–2 pCi/L (37–74 Bq/m^3). One becquerel/m^3 represents 60 decays per minute per cubic meter. When sampling a cubic meter of air at the same location, Bq/m^3 will always be numerically larger than the corresponding pCi/L; however, when sampling a liter of water, 1 pCi/L represents 0.037 Bq/L. Table 38.8 displays the conversion factors for converting traditional units of radon activity (Ci), concentration (pCi/L), and exposure (WLM) to SI units.

TABLE 38.8. Physical quantities and units used to quantify radon and radon progeny with conversion factors for traditional to SI units.

Quantity	SI Unit (Symbol)	Traditional Unit (Symbol)	Conversion Traditional to SI Units
Activity	Becquerel (Bq)	Curie (Ci)	1 Ci = 3.7×10^{10} Bq
Concentration	Bq/m^3	pCi/L	1 pCi = 37 Bq/m^3
Exposure	J-s/m^3	Working level (WL)	1 WLM = 12.97 J-s/m^3 = 0.0036 J-hours/m^3
Exposure rate	J/m^3	WLM	1 WLM/year = 4.11×10^{-7} J/m^3
PAEC	J/m^3	WLM/year	

Abbreviation: PAEC = potential α-energy concentration; WLM = working level month.

Working Level

The working level (WL) measures intensity and duration of radiation exposure from radon progeny; the definition of this unit is any combination of radon progeny in 1 L of air that results in the emission of 1.3×10^5 MeV of α-particle energy. At equilibrium, 1 WL = 100 pCi/L; however, rapid dispersion of radon progeny in indoor air usually prevents the attainment of equilibrium. For general calculations, 1 WL for *indoor* radon progeny equals ~200 pCi/L (50% equilibrium), ~300 pCi/L (33% equilibrium) for an underground *mine*, and ~150 pCi/L (67% equilibrium) for *outdoor* area.[146] The WL assumes that all α-activity is the same, whereas a small portion of unattached radon progeny possess greater biological impact.

Working Level Month

The working level month (WLM) was designed for epidemiological studies of miners as a measure of cumulative exposure (i.e., intensity × duration). The working level month (WLM) is equivalent to the exposure of 1 WL for 170 hours. None of these units directly measure the absorbed radiation dose; the latter depends on biological factors including the pattern and extent of breathing, the characteristics of the inhaled aerosol, physiological parameters in the lung (mucous thickness and clearance), exposure duration, and the location of target cells.[60,147] The conversion coefficient for annual indoor home exposures to radon adopted by the International Commission on Radiological Protection (ICRP 65) is 1 WLM = 4 mSv assuming 7,000 hours indoors and an equilibrium factor of 0.4, whereas at work, assuming 2,000 annual work hours and a similar equilibrium factor, the annual radon exposure is 5 mSv.[148] Assuming different occupational and residential durations of radon exposure, 1 WLM ≅ an average annual residential exposure of 230 Bq/m^3.[149]

Analytic Methods

Residential radon concentrations are difficult to predict using models based on soil porosity, foundation type, location, building materials, ventilation rates, water supply, or entry points for soil gas. Most US detectors provide an initial rapid screening measurement to detect the maximum radon concentrations in the home. Although the US EPA offered a proficiency program certifying accuracy (≤25% at 4 pCi/L) and precision (coefficient of variation ≤10%) for radon testing until 1998, the accuracy of these tests at radon concentrations in most homes (1–2 pCi/L) is probably less (e.g., ~50%).[150,151] The length of monitoring depends on the analytical procedure. Screening tests should be performed in the lowest portion of the house with the windows and doors closed for at least 12 hours. Ventilation of the room being tested should be minimized, usually during the coolest months of the year. Because the radon concentration varies with time of day, season, and location in the home, the results should be considered a screening technique indicating the potential for excessive radon exposures.[152] Screening measurements usually provide overestimates of the actual radon exposure.

The two categories of devices used to measure air radon and radon progeny include 1) passive devices (e.g., activated charcoal absorption) and 2) continuous monitor devices. The former monitors average radon concentrations over time, operates without power, and requires laboratory analysis to obtain results, whereas the latter measures radon gas in relatively small increments (e.g., <1 hour), typically requires power to operate, and supplies continuous readings for either radon or radon progeny. Some passive devices (e.g., activated charcoal absorption) allow adsorbed radon to undergo radioactive decay during the measurement period, whereas others (e.g., α-track detection) use a small piece of plastic or film enclosed in a container with a filter-covered opening to permit the passage of radon but not radon progeny.

Commercial devices for quantitating radon concentrations in homes include activated charcoal detectors, α-track detectors, continuous monitors, Electret ion chambers, and electronic integrating devices. All these devices measure short-term radon exposures (i.e., few days to a few months), whereas the latter three devices are suitable for long-term monitoring (i.e., months to years). The simplest, least expensive method of detecting indoor radon is a canister filled with 20–50 g of charcoal that adsorbs radon passively over 2–7 days; subsequently, a γ-ray detector measures the radiation level in the material. The solid-state nuclear track detector records the decay of radon progeny on a special polycarbonate plastic film that records the number of α-particles striking the film. A caustic solution accentuates the submicron damage caused by the α-particles; an automated counting unit or a microscope tabulates the amount of radon. These solid-state detectors remain in place for 1–12 months. The scintillation cell method continuously measures the radon concentration by detecting the number of α-particles emitted by radon and radon progeny trapped in a particulate filter on a continuous pump. A photomultiplier tube generates an electrical signal when the α-particles produce scintillations inside the scintillation cell. Long-term testing methods (solid-state detectors, Electret ion detectors) are the most accurate methods of screening homes for elevated radon concentrations.

Biomarkers

The ionizing radiation dose determines the biological effects following exposure; these effects are not unique to radon and radon progeny. Although the presence of radon progeny in tissues indicates exposure to radon, ingestion of food- or water-containing radon-producing radionuclides (e.g., uranium and thorium) also produces these decay products. Additionally, the short half-lives of many decay products determine the presence of these radionuclides after exposure. Measurements of radon in blood or urine are not practical biomarkers because of the 3.8-day half-life of radon, whereas analysis of long-lived radon progeny (e.g., ^{210}Pb, ^{210}Po) in biological samples suggests radon exposure. However, these radionuclides are not unique biomarkers of radon exposure because a variety of sources emit them. Consequently, estimation of radon exposure typically involves the analysis of environmental samples.

In vitro studies demonstrate a significant increase in the frequency of dicentrics, excess acentric fragments, and centric rings with increasing **radon** doses, whereas total acentric rings plus double minute and chromatid breaks/cell were not significantly elevated.[153] Epidemiological evidence for chromosomal abnormalities following residential radon exposure is conflicting; however, studies of uranium miners have not demonstrated excess dicentrics or translocation despite radon exposures substantially higher than residential radon exposure.[154] These studies detected no significant difference between miners and controls in the frequencies of chromosome- and chromatid-type aberrations; additionally, the frequency of translocations did not correlate to the estimated radon dose. In a German study of chromosomal aberrations in peripheral lymphocytes of Wismut uranium miners in East Germany and Ruhr coal miners, the frequencies of chromosomal aberrations and sister chromatid exchanges were attributed to age, diagnostic radiation, illnesses, medications, and lifestyle rather than radon exposure.[155] Cells with multiple chromosome aberrations (rogue cells) occur in different populations, primarily following radiation exposure. Several studies have associated rogue cell formation with radon exposure;[156] however, the etiology of rogue cells remains unclear.

HEALTH SURVEILLANCE

Risk Assessment

Although epidemiological studies clearly indicate radon is a human carcinogen, animal studies demonstrate substantial variation in the sensitivity of animal species to radon-induced cancer with rats and dogs being relatively sensitive and hamsters and mice being relatively insensitive up to doses exceeding 10,000 WLM. Consequently, the wide variation in animal responses and insufficient data on the mechanisms of interspecies variation seriously limit animal-to-human extrapolation in risk assessment.[57]

Models

Relative Risk

Most analyses of cancer risk from radon use the linear excess relative risk (ERR) model where the excess risk is the product of the risk coefficient measuring the unit increase in ERR per unit increase in cumulative exposure (e.g., unit/100 WLM) and the lifetime cumulative radon progeny exposure without a threshold. The relative risk is then 1 + ERR. The ERR per unit of exposure varies with age, time since exposure, and time since exposure ceased.[157] Table 38.9 lists the features of the risk models for radon-induced lung cancer developed by the NCRP, ICRP, and BEIR IV Committee based on uranium miner data published before and during the 1980s. These studies typically used cohort designs with retrospective assessments of radon exposure. The BEIR VI Committee updated the risk data from recent studies of uranium miners by developing 2 preferred risk models (exposure-age-concentrations, exposure-age-duration) after evaluating data from ~60,000 miners in 11 cohort studies (8 uranium and remainder fluorspar, iron, and tin). The Committee retained the linear, non-threshold relationship between lung cancer risk and radon exposure after excluding cumulative radon exposures exceeding 3,200 WLM; however, the Committee acknowledged that threshold and curvilinear relationships could not be excluded at low radon concentrations. Both the relative and absolute excess risk models fit the available epidemiological data. The predicted lung cancer risk depends on the model chosen and the assumptions accepted by the expert groups. The relative risk model (ICRP, BEIR IV) assumes that the risk from radon is a multiple of the background cancer risk with the risk varying by age, sex, and smoking history.

Relative risk models are usually easier to use; this type of model forecasts the most conservative risk estimates, particularly in older age groups that have a high mortality rate from underlying lung cancer.[102,159] The ICRP model uses a constant relative risk model, which forecasts the highest risk of lung cancer. The US EPA uses a constant relative risk model with relative risks ranging from 1–4% per WLM and with adjustments for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 38.9. Characteristics of risk models created by the National Council on Radiation Protection and Measurements (NCRP), International Commission on Radiological Protection Publication 50 (ICRP 50), and Committee on the Biological Effects of Ionizing Radiation IV (BEIR IV) for radon-induced lung cancer. (Adapted from Samet).[158]

Characteristic	NCRP	ICRP 50	BEIR IV
Model type	Attributable risk	Relative risk	Relative risk
Time-dependence after exposure	Risk declines exponentially	Time-independent	Risk declines as time increases
Lag interval (years)	5	10	5
Age at exposure	Increased risk for childhood exposure	3-fold increased risk for exposure at ≤20 years of age	No adjustment
Age at risk	Risk starts at age 40 years	Age-related relative risk is constant	Lower risk for ages ≥55 years
Dosimetry adjustment	Increased risk for indoor exposure	Decreased risk for indoor exposure	No adjustment
Risk coefficient	10×10^{-6}/year/WLM	ERR: 1.9%/WLM age ≤20 years; 0.64%/WLM age ≥21 years	ERR: 2.5%/WLM modified by time since exposure

Abbreviation: ERR = excess relative risk.

minute ventilation (15.3 L air/minute). Analysis of data from the cohort of Eldorado uranium workers indicates that the increased risk of lung cancer following exposure to radon decay products is linear with increasing exposure.[160] The increased risk of lung cancer mortality in the cohort ($n = 618$) using a simple linear model was 5.5%/WLM (95% CI: 3.7–7.8%). The risk of lung cancer mortality for cumulative exposure of <100 WLM was relatively small. Smoking data were unavailable for the cohort. The relative risk of developing lung cancer from radon exposure diminishes with increasing time since the exposure ceased. In miners, shorter durations and higher radon exposure rates have a lower risk of developing lung cancer than the same total radon exposure over a longer period of time.[161]

Absolute Risk

Differences in study population characteristics (e.g., time since exposure, age attained) complicate the comparison of individual study results. Lifetime excess absolute risk (LEAR) allows the comparison of different risk models for different populations with the same exposure scenario. The attributable risk model (NCRP) assumes that excess risk is additive to the background level of risk; the risk is independent of smoking and age before 40 years. The NCRP model usually predicts the lowest excess risk because the additive model assumes the risk of developing lung cancer decreases over time.[162] Absolute risk models tend to overestimate risk at lower ages and underestimate risk at higher age groups. The validity of this model is better in the age group >40 years and with longer latency periods.[95] The minimal latency period for the BEIR VI and NCRP models is 5 years, whereas the ICRP model uses 10 years. The updated ICRP lifetime excess absolute risk based on occupational exposure studies is ~0.0005/WLM (14×10^{-5}/mJh/m^3).[149] This value depends on the background mortality rates. Using lung cancer rates of Euro-American males instead of ICRP reference rates, the estimated absolute risk is higher (LEAR = ~0.0007/WLM (20×10^{-5}/mJh/m^3).

Uncertainties

Radon is ubiquitous in all environments on earth. The key areas of controversy include whether the same risk factors derived from the higher radon exposure level present in mines apply to radon exposure in homes including the following: 1) the duration of radon exposure may modify (e.g., by cellular repair processes) the risk factors for lung cancer, 2) the use of different detectors in mines and homes, 3) equilibrium conditions, and 4) the presence of other carcinogens (e.g., arsenic, γ-radiation, thoron);[43] additionally, substantial diurnal and season–season variation in indoor radon concentrations occurs with changes in weather patterns and occupant behavior (temperature preferences, window opening).[44] Figure 38.6 displays the uncertainties associated with lung cancer mortality risks from high-dose miner data to low-dose residential radon exposures. Dosimetric modeling can correct some, but not all, problems when extrapolating high-dose miner data to the general population. Current comparative estimates suggest relatively similar types of radon progeny doses in homes and mines.[163]

Smoking

Smokers account for ~85% of radon-induced lung cancer cases.[164] Although the large majority of lung cancers occur in smoking miners, an increased incidence also occurs in nonsmoking miners with epidemiology

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 38.6. Sources of uncertainty when extrapolating high-dose radon data to low-dose radon data. Models estimating radon-associated lung cancer risks initially extrapolated data from earlier epidemiology studies on uranium miners exposed to relatively high radon doses to lower indoor radon concentrations. More recent epidemiology studies on the exposure of miners to low radon doses similar to residential exposures and analyses of pooled data from residential case-control studies of lung cancer risks improved the estimation of lung cancer mortality risks associated with radon exposure. (Adapted from Samet et al.).[44]

data suggesting radon exposure causes a relatively greater portion of lung cancer cases in nonsmokers than smokers.[165] Many analyses suggest the contribution of smoking to the risk of developing lung cancer after radon exposure is more (but not completely) multiplicative than additive.[42,166] Reanalysis of the mining data by the BEIR IV and VI committees suggests that the effect of smoking and radon exposure is more than additive but less than multiplicative with a wide confidence interval (ERR/WLM = 3.0, 95% CI: 0.3–29.2).[83] Increased radon-induced lung cancer risks persist after controlling for smoking habits. In a European study of 1,046 lung cancer cases and 2,492 controls in three uranium mining cohorts with detailed radon exposure data and smoking status, time since exposure was the major modifier of the effect of radon exposure on lung cancer risk.[167] The excessive relative risk for lung cancer remained elevated after adjustment for smoking (ERR = 0.0079/WLM, 95% CI: 0.0044–0.0141). The predicted lifetime lung cancer excess mortality of smokers is much greater in the ICRP and BEIR VI models using multiplicative models compared with the NCRP model using the additive model.[168] Smoking information was available in some uranium miner studies evaluated by the BEIR VI Committee. The average increased lung cancer death rate in the studies with smoking information was 0.0053/WLM (95% CI: 0.002–0.0138), similar to the overall average of the 11 studies. The average increased radon-induced lung cancer death rates/WLM were elevated in never-smokers (0.0102/WLM, 95% CI: 0.0015–0.018/WLM) compared with the combined group of current and ex-smokers (0.0048, 95% CI: 0.0018–0.0127); however, the difference was not statistically significant. In a nested case-control lung cancer mortality study of 704 deceased German miners and 1,398 controls matched for birth year and attained age, the crude ERR/WLM was 0.0025 (95% CI: 0.0013–0.0046).[169] The smoking-adjusted ERR/WLM using conditional logistic regression was similar (0.0023, 95% CI: 0.0011–0.0046) assuming smoking was a multiplicative factor. Smoking history was reconstructed retrospectively with questionnaires and company records. A case-control study of 308 Chinese women with lung cancer found no difference between radon concentrations in the homes of the lung cancer cases and the control group regardless of smoking status.[170]

Occupational Exposure

Initial estimates of radon health effects were derived from excess lung cancer mortality occurring in cohort studies of uranium miners frequently exposed to radon doses of >100 WLM in their early work years (i.e., before 1970); the radon exposure was usually estimated retrospectively in working level months (WLM). Risk estimates for lung cancer deaths vary substantially between studies and mines. The estimated relative excess of lung cancer mortality in several studies differed by an order of magnitude (i.e., 0.0027–0.03 cases/WLM).[158,171] Overall excess relative risk (ERR) estimates of lung cancer mortality in 5 analyses of pooled cohorts involving ~300,000 miners and ~6,000,000 person-years ranged from 0.0049–0.0160/WLM with the highest ERR in the combined cohort with the lowest radon exposure.[149] Variation in cohort characteristics potentially accounts

for the differences in ERR including background lung cancer rates, radon exposure levels, attained age, duration of work, and follow-up time.

In an analysis of pooled data from 11 cohort studies involving ~60,000 miners, the Committee on the Biological Effects of Ionizing Radiation (BEIR VI) estimated an overall, average excess lung cancer death rate of 0.0044/WLM (95% CI: 0.002–0.01/WLM).[102] The estimated size of the increased risk of lung cancer-related deaths varied by a factor of 10 between the 11 studies. Using the exposure-age-concentration BEIR VI model, the highest ERR was ~0.077/WLM for a miner with an attained age below 55 years after 5–14 years of exposure to a low radon dose (<0.5 WLM). The average increased lung cancer rate/WLM of 0.0021 (95% CI: 0.0018–0.0024) for an East German uranium miner (Wismut) cohort, nearly as large as the combined pool in the BEIR VI assessment and was ~1/2 the average BEIR VI rate. Smoking data were not available for miners in the East German cohort.

Lung cancer mortality risk (i.e., estimated excess relative risk or ERR/WLM) for a 30-year-old miner with 20 years of exposure to cumulative radon doses lower than older studies ranged from 0.004 (95% CI: <0.01–0.04) in the Port Hope uranium processor cohort[172] to 0.042 (95% CI: 0.022–0.067) in the French/Czech pooled miner cohort.[173] The excess relative risk (ERR) of lung cancer/WLM in a subcohort of 26,766 German uranium miners hired before or after 1960 was 0.013 (95% CI: 0.007–0.021) with a linear relationship to radon exposure; the mean age at first employment was 21 years (range, 13–68 years), and the mean duration of employment was 10 years (range, 0.5–30 years).[174] The mean cumulative exposure was 17 WLM with a maximum of 334 WLM. A study of Swedish iron mine workers employed from 1923–1996 and followed from 1958–2000 identified 122 lung cancer cases. The excess relative risk (ERR/kBq-year/m^3) was 0.046 (95% CI: 0.015–0.077) and 0.022/WLM.[175] Quartz exposure confounded the risk estimates, accounting for <20% of the excess. The average cumulative radon exposure was 65 WLM over 14.6 years. Statistically significant excess deaths were attributed to squamous cell and small cell lung cancers, but not adenocarcinoma lung cancer.

Residential Exposure

Earlier residential studies used ecological designs to compare average radon concentrations and average lung cancer rates in different geographic regions. The inability to control confounding variables (e.g., smoking, other carcinogens) and accurately estimate cumulative radon exposures resulted in biased, potentially misleading estimates of true radon-related lung cancer risks. Although most case-control studies have insufficient power to detect increased lung cancer risks from radon exposure, 3 studies derived pooled estimates from similar residential studies of radon-induced lung cancer risks by collating and comparing individual information from 13 European studies,[176] 7 North American studies,[177] and 2 Chinese studies.[178] The average radon exposure was 30 years with a minimum lag time of 5 years prior to diagnosis and adjusted for smoking.

Thresholds

Analysis of European data from 7,148 persons with lung cancer and 14,208 age- and sex-matched controls demonstrated an excess relative risk of lung cancer mortality after controlling for confounding; these data suggested a statistically significant excess risk of lung cancer mortality following time-weighted, average annual radon exposures of ~200 Bq/m^3 for 5–34 years. There was no evidence that the excess relative risk varied with age, sex, or smoking history. The dose-response relationship was linear without evidence of a threshold including residents with radon exposures of <200 Bq/m^3.[176] Figure 38.7 displays the best-fitting straight line and the 95% confidence intervals for the European pooled study with an x-intercept of 0 Bq/m^3 (i.e., no threshold). A New Jersey study of 561 lung cancer cases and 740 local controls suggested an increased lung cancer risk for residential exposures exceeding 75 Bq/m^3 (excess odds ratio = 0.05, 95% CI: −0.14 to 0.56); however, the excess was not statistically different from controls.[179] Some studies suggest the linear no-threshold model is not the best fit for lung cancer risk at radon levels below 400–800 Bq/m^3.[180] A follow-up study of *nonsmoking* miners in the Colorado Plateau study did not detect any cases of lung cancer in workers with cumulative radon exposures below 465 WLM (1 WLM is equivalent to an annual exposure to 200 Bq radon progeny from mines/m^3).[165]

Relative Risk/Odds Ratio

Direct comparisons of lung cancer risks from radon exposure during occupational and residential exposures are complicated by differences in radon exposure and the inverse exposure-rate effect at the higher radon concentrations in uranium mines, particularly during earlier years. Uncertainties extrapolating lung cancer risk from radon exposures in miners to residents of homes with radon exposure include age, different radon concentrations, and exposure misclassification associated with retrospective analyses reflecting differences in ventilation

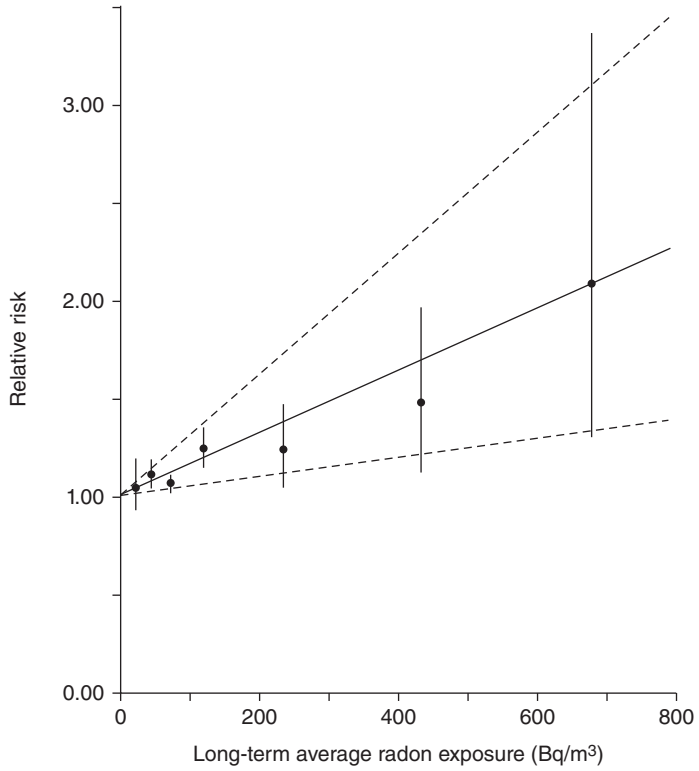

FIGURE 38.7. Relative risks and 95% confidence intervals (dotted lines) for long-term radon exposure with the solid line representing the best-fitting straight line based on pooled data from 13 European studies by Darby et al.[65] The risk at 0 Bq/m^3 represents the background lung cancer rate, set at 1.00. (Zeeb and Shannoun).[181]

and activities during radon exposure.[182] Case-control studies of residential exposure indicate an increased relative risk of lung cancer from long-term radon exposure depending on several factors including age at exposure, age attained, and cumulative radon dose.

Although organs other than the lung (e.g., kidneys, bone marrow) receive low radiation doses following residential radon exposure,[76] there is no clear evidence that residential radon exposure increased the rates of nonpulmonary cancers including leukemia.[183] Positive studies are typically ecological studies subject to a substantial number of biases. The Iowa Radon Leukemia Study reported excess rates of leukemias associated with radon exposure including chronic lymphocytic leukemia (CLL);[184] however, this type of leukemia is not usually associated with radiation exposure.

Excess Relative Risk/Excess Odds Ratio

Excess relative risk (ERR) for lung cancer in a population exposed to radon is the ratio of lung cancer rate in the exposed population to the lung cancer rate in the unexposed population minus one (i.e., the background rate). Theoretically, the ERR should be the same as the attributable risk; however, in practice, the ERR is calculated from an observed effect (e.g., lung cancer), whereas the attributable risk is calculated from an estimated or observed exposure (e.g., radon). Excess relative risks for residential exposures are usually expressed as radon concentrations (pCi/L, Bq/m^3), whereas occupational exposures are expressed as radon progeny concentrations (WL, WLM). Typically, summary risk estimates are somewhat lower for uranium miners than residential studies. The ICRP model yields a risk lung cancer coefficient of ~0.035/Sv as an effective dose equivalent, whereas the NRPB model estimates a risk coefficient of 3×10^{-10}/Bq-h/m^3 as an integrated radon concentration. The overall joint estimate of the excess risk of lung cancer in the European, American, and Chinese pooling studies based on radon measurements in residences was 0.01/100 Bq/m^3 consisting of 0.08/100 Bq/m^3 (95% CI: 0.03–0.16/100 Bq/m^3) for the European pool, 0.11/100 Bq/m^3 (95% CI: 0–0.28/100 Bq/m^3) for the American pool, and 0.13/100 Bq/m^3 (95% CI: 0.01–0.36/100 Bq/m^3) for the Chinese pool.[181]

Individual residential studies of residential radon exposure demonstrate substantial variability in alculating the ERR. Using conditional likelihood regression to

estimate the excess risk of lung cancer due to prolonged residential radon exposure demonstrated an excess odd ratio (EOR) of 0.18 (95% CI: 0.02–0.43)/100 Bq/m^3 after adjustment for attained age, sex, study, smoking factors, residential mobility, and completeness of radon measurements.[177] The estimated EOR was compatible with an EOR of 0.12 (95% CI: 0.02–0.25)/100 Bq/m^3 predicted by downward extrapolation of the miner data. In a similar study of pooled data from 13 European studies of prolonged (e.g., 25 years) residential radon exposure and lung cancer, the excess relative risk of lung cancer/100 Bq/m^3 was 0.08 (95% CI: 0.03–0.16; $P = 0.0007$) after controlling for confounding.[176] In the prospective Cancer Prevention Study II cohort of 1.2 million participants using ecological radon data, 3,493 lung cancer deaths occurred during the first 6 years of follow-up.[185] Categorizing the cases by radon exposure evaluated at the beginning of the study demonstrated an increased lung cancer mortality risk of 0.15 (95% CI: 0.1–0.31)/100 Bq/m^3 with the risk increasing to 0.34 (95% CI: 0.07–0.68)/100 Bq/m^3 for initial radon exposures exceeding the USEPA guideline recommending an upper limit of 148 Bq/m^3.

Biological Monitoring

Although models have been developed to estimate exposure to radon and radon progeny using long-lived radon progeny (^{210}Pb, ^{210}Po) in teeth, bone, and blood, numerous uncertainties limit the accuracy of these models including the spatial distribution of radon decay progeny and the ubiquitous presence of radon, ^{238}U, and ^{226}Ra.[186,187] Consequently, these models are not useful biomarkers of exposure for quantifying exposure to radon and radon progeny. Epidemiological studies of uranium and lead-zinc miners exposed to radon demonstrate an increased incidence of structural chromosomal abnormalities compared with the general population. In a study of US uranium miners, the correlation between chromosomal aberrations and radon dose was variable.[188] The prevalence of deletions and dicentrics plus rings correlated poorly with radon dose, particularly in the miners exposed to >3,000 WLM. Pericentric inversions and translocations consistently increase with radon dose. The frequency of total chromosomal aberrations persists for years after cessation of radon exposure in uranium miners.[189] In a study of 70 workers from a lead-zinc mine, total structural chromosome aberrations decreased significantly from 5.08/200 metaphases in 1995 to 3.28/200 metaphases in 1997, when the mine closed.[190] These values were significantly different from the control group of local inhabitants never employed in the mine (1.43/200 metaphases). Sister chromatid exchanges correlated more closely to heavy metal concentrations than radon concentrations; the latter exposure was high in some portions of the mine (3,000–5,000 Bq/m^3). The interactions of radon with genotoxic substances (e.g., arsenic, cigarette smoke, crystalline silica dust, diesel exhaust particulates, heavy metals) complicate studies correlating radon exposure with intrachromosomal aberrations (pericentric inversions, centric rings, acentric fragments), interchromosomal aberrations (translocations, dicentric/acentric fragments), and sister chromatid exchange between two sister chromatids. Consequently, these genotoxic effects are not exclusively attributable to radon exposure, limiting the usefulness of chromosomal aberrations as biomarkers of radon exposure.

The exfoliated-cell micronucleus assay is a noninvasive, cytogenetic technique for monitoring the mutagenic and carcinogenic potential of chemical exposure. Chromosomes or fragments from chromosomes remain in the cell cytoplasm when DNA fails to incorporate into a progeny nucleus. These DNA fragments form micronuclei in the cell cytoplasm. Use of this cytogenic technique on the sputum of uranium workers is not an effective technique for determining exposure to radon or cigarette smoking.[191] Direct measurements of radon and radon progeny in biological media (serum, urine, teeth, hair) are not practical markers of radon exposure.[57,83]

Environmental Monitoring

Radon exposure should be kept as low as reasonably achievable (ALARA) with regulations and guidelines setting upper exposure limits. The ICRP recommends an upper limit of radon exposure of 200 Bq/m^3 (5.4 pCi/L) for buildings on which remedial action is economically feasible. Using the ICRP model, the National Radiological Protection Board calculated that a lifelong exposure to an average radon concentration of 200 Bq ^{222}Rn/m^3 air corresponds to a lifetime risk for the general population of 3% (10% for smokers, 1% for nonsmokers).[192] For new buildings, their recommendation is 100 Bq/m^3 (2.7 pCi/L). The World Health Organization (WHO) endorses an upper average annual radon limit of 100 Bq/m^3 (2.7 pCi/L air) for remedial action. In 2014, the ICRP reduced the upper reference radon level for homes to 300 Bq/m^3 in response to a doubling of the ICRP detriment-adjusted nominal risk coefficient for lung cancer in a mixed adult population of nonsmokers and smokers to 8×10^{-10}/Bq h/m^3 for ^{222}Rn

gas in equilibrium with its progeny (5×10^{-4}/WLM).[193] The reference value of 300 Bq/m^3 corresponds to an annual effective radiation dose of ~10 mSv. Considering the prevailing social and economic circumstances, the Commission recommended reducing the radon level in homes as low as reasonably achievable in the range of 100–300 Bq/m^3. Although 1,000 Bq/m^3 was the recommended entry point for applying occupational radiological protection requirements in 2010,[81] the Commission recommended replacing this value with a specific graded approach that included reducing radon concentrations to levels as low as reasonably achievable below the reference level set for dwellings (<10 mSv/year). The upper value of the range of existing exposure situations should not exceed 20 mSv/year, regardless of whether the worker is occupationally exposed to radon or not.

As outlined in Table 38.10, the action level for remedial action recommended by the US EPA is 4 pCi/L (150 Bq/m^3).[194,195] At this action level, the risk of

developing lung cancer is slightly above the lung cancer risk for the general population; however, further reduction of radon may be costly and difficult to complete.[196] The risk of developing lung cancer at this level increases by ~50%, which is approximately equivalent to the lung cancer risk from smoking 1/2 pack of cigarettes/day or receiving 200 chest X-rays/year. This EPA guideline is a recommendation rather than a strict boundary between safe levels and levels producing substantial lung cancer risks.[162] Hence, the decision to use mitigating measures at radon levels near 4 pCi/L depends on a risk-benefit analysis. The original regulations for radon exposure in uranium mines allowed an exposure of 12 WLM of radon progeny/year; however, the regulatory level decreased to 4 WLM of radon progeny/year in 1971.[146] Statistically significant, excess lung cancer mortality occurred in a Czechoslovakian cohort of miners at cumulative radon exposures of <50 WLM,[197] whereas excess lung cancer deaths appeared in US and Canadian miners at cumulative exposures of >100 WLM.[198] Although the US EPA recommends 4 pCi/L as the current action level for all occupied buildings as displayed in Table 38.10, the EPA does not exclude an increased lung cancer risk for indoor radon concentrations of <4 pCi/L (148 Bq/m^3).[199] The EPA encourages cessation of smoking as a mitigating factor for radon-associated risks.

TREATMENT

Remedial Methods

There are no methods to reduce radon absorption or body burden. Dietary supplements are not recommended for the prevention of radon-induced lung cancer.[200] The US Surgeon General and the US EPA recommend testing all homes for radon concentrations; substantial variation occurs in radon concentrations during short-term tests as a result of diurnal and seasonal variations. Soil beneath a dwelling is the most common residential radon source. Simple, inexpensive methods to reduce radon exposure include avoiding areas (e.g., basements) of high radon concentrations, venting basements and crawl spaces to the building exterior, and improving house ventilation. Radon concentrations remain low in well-insulated, well-sealed dwellings following the construction of effective vapor barriers that prevent radon diffusion into the dwelling.[201] Other methods to reduce radon concentrations include natural, heat recovery or forced ventilation, covering exposed earth, sealing cracks and openings, drain-tile or sub-slab suction, block wall ventilation, prevention of house depressurization, and basement pressurization.[202,203] Smoking substantially potentiates the radon-induced lung cancer risk; consequently, the most effective way to reduce radon-induced lung cancer is to reduce smoking prevalence.[204] Table 38.11 compares smoking and radon risks along with guidelines for repeat measurements and remedial action timelines.

The goal of remediation is the reduction of indoor radon concentrations to the outdoor concentration (i.e., 0.4 pCi/L in the United States) and lower if possible. Properly designed active soil ventilation systems (e.g., suction on perimeter drain tiles) are usually the most effective technique (i.e., 90–99% decrease) when a complete loop of drain tiles exists. Sub-slab suction is the next most effective method based on a study by the US EPA.[205] Ventilation of block wall cavities produces less predictable results. Heat recovery ventilation is moderately effective (i.e., ~50% reduction). The actual reduction in the radon concentrations varies between houses as displayed in Table 38.12; testing with different types of remedial measures may be necessary to achieve permanent reductions in the radon concentration. The effectiveness of each remedial

Sump-hole suction	Air	50–99%
Activated charcoal	Private well water	85–99%
Aeration	Private well water	95–99%

technique should be confirmed by comparing measurements using the same method. Carbon filtration is an effective technique (i.e., 95–99% reduction) to remove radon from water. The outcome of radon mitigation techniques depends on several factors including climate, soil conditions, building type, and source.[206] Empirical evidence for screening individuals with low-dose CT imaging similar to high-risk lung cancer groups (current smokers or former smokers having quit within the past 15 years and aged 55–80 years with ≥30-pack year smoking history) is insufficient to recommend CT screening at this time for specific radon exposures; however, the US Preventive Services Task Force recommendations have been reviewed.[207,208]

Initiating Remedial Measures

Table 38.11 outlines a timeline for repeat radon measurements and remedial actions following elevated radon concentrations during screening based on recommendations by the US EPA. The decision to perform remedial action depends on a variety of factors, including 1) presence of children, 2) amount of time spent in areas of high radon concentrations, 3) percent of time spent at home, 4) anticipated length of ownership, and 5) associated risk factors for the development of lung cancer (smoking, occupational exposure to lung carcinogens).[196]

Chapter 39

IONIZING RADIATION INCIDENTS

PHYSICAL PROPERTIES

Alpha Particles

Alpha-emitting radionuclides release α-particles (two protons, two neutrons) from their nucleus along with a characteristic amount of energy. These particles rapidly decay while acquiring electrons from the surrounding environment to become inert ^{4}He; the typical lifetime of an α-particle is a few picoseconds. Alpha particles possess high linear energy transfer; therefore, these particles cause substantial damage at short range compared with β-particles. Because the relatively heavy α-particles travel at a comparatively low speed, they spend more time near the atoms and exert more impulses on the orbital electrons. Consequently, α-particles are particularly hazardous at short range because of the large amount of radiation imparted locally. The main determinant of tissue penetration is the energy of the particle. For charged particles (e.g., α- and β-particles) with the same energy, the depth of penetration depends on the size of the particle and its charge.

Alpha particles are the main source of radiation exposure for uranium miners breathing radon gas and workers ingesting radium or thorium isotopes while producing radio-luminescent dials. The internal absorption of the α-particles in these workers increases the risks of lung and bone cancers. An α-particle requires at least 7.5 MeV of energy to penetrate the keratin layer of the skin; therefore, α-emitting particles are hazardous only if ingested or inhaled. Table 39.1 compares the physical characteristics of the types of ionizing radiation involved in incidents related to the release of ionizing radiation.

Beta Particles

Beta particles are high-speed, negatively charged electrons released during the radioactive transformation of a neutron into a proton. The energies of the β-particle released from radioactive decay form a spectrum of energies ranging up to a maximum (E_{max}) characterized by the specific transformation involved. Hence, most β-particles emitted during the transformation do not possess the maximum potential energy (E_{max}). The difference between the maximum energy and the energy of the β-particle results from the emission of a neutrino from the nucleus. However, the neutrino does not interact with matter; therefore, the neutrino does not produce ionization or damage to the tissue.

Gastrointestinal absorption of β- and α-particles produces internal damage. The energy of the β-particle determines its ability to penetrate the skin and cause external damage. The maximum potential energy (E_{max}) for tritium is 0.018 MeV; this value is lower than the energies of electrons hitting most television screens. These β-particles are too weak to penetrate human skin in contrast to the high-energy β-particles from ^{32}P that penetrate up to 8 mm into the body.[1] Skin burns from high-energy β-particles were a major contributing factor to mortality in workers exposed to radiation exceeding 1 Gy at the Chernobyl accident in 1986.[2]

TABLE 39.1. Physical characteristics of radiation commonly emitted from radioactive sources. The exact depth of radiation penetration in human tissue depends on a variety of factors including wavelength, mass, tissue composition (melanin, water), interactions of radiation with tissue (absorption, scattering), and the angle of observation (anisotropy).

Physical Character	α-particles	β-particles	γ-rays	X-rays	Neutrons
Symbol	α	β	γ	X	n
Composition	2 protons, 2 neutrons	1 electron	Electromagnetic wave	Electromagnetic wave	Free neutrons
Mass (amu)	4	0.0005	0	0	1
Charge	+2	±1	0	0	0
Energy (MeV)	4–8	0–3	0–3	0–0.5	0–5
Range (air)	Few cm	≤several meters	Many meters	Many meters	Many meters
Range (skin, soft tissue)	50 μm	Few mm	Many cm	Many cm	Many cm
Hazard	Internal	Internal-external	Internal-external	Mostly external	External

Gamma Rays

Gamma rays are "pure" electromagnetic waves (i.e., no mass/charge) that are emitted from radioactive nuclei; γ-rays often accompany the release of β-particles. Although γ-rays have the same range of energies as β-particles, a specific radionuclide releases discrete energy rather than the range of energies up to the maximum (E_{max}) that occurs with β-particles. Beta particles ultimately stop in the tissue and combine with an atom, whereas γ-rays travel at the speed of light through tissue until they lose energy due to the ejection of an electron during a chance encounter with an atom. The depth of penetration depends on the interaction of the γ-rays with the atoms in the tissue. The probability that a γ-ray will penetrate through tissue depends on the thickness and composition of the medium in addition to the energy of the γ-ray.

Gamma rays are indirect ionizing radiation with tissue damage resulting from electrons ejected by chance collisions rather than directly from interaction with the tissues. As with all indirectly ionizing radiation, some radiation will penetrate any shield depending on the amount of activity and the strength of the shield, whereas a β-shield will stop all β-particles within the maximum range.

X-Rays

Although X-rays and γ-rays are "pure" electromagnetic radiation, the origins of these two types of radiation differ. X-rays are photons emitted from electron shells or decelerating charged particles (e.g., electrons), whereas γ-rays originate from the atomic nucleus or particle annihilation. The emission of X-rays typically occurs when electrons in excited atomic shells transition to lower energy states. The deceleration or deflection of electrons in an electromagnetic field close to the nucleus produces a continuous X-ray spectrum characteristic of the corresponding element (e.g., tungsten). The classification of medical X-rays involves peak applied voltage (kVp) that varies from ultra-soft (5–20 kVp) to very hard X-rays (>250 kVp) produced by betatrons and linear accelerators.[3]

Neutrons

Other than the production of neutrons from the decay of ^{252}Cf (californium-252), exposures to neutrons occur from human activity through nuclear reactions (e.g., nuclear-fission reactors, high-energy accelerators). Neutrons are uncharged; therefore, these particles do not interact easily with tissue. In contrast to the interaction of X-rays and γ-rays with orbital electrons, neutrons interact with the atomic nucleus. They are indirectly ionizing particles that produce damage in the tissue by striking atomic nuclei (primarily hydrogen) and producing mostly highly charged, slow-moving recoil protons. The energy from recoiling atoms possesses high linear energy transfer that causes comparatively more tissue damage than β-particles or γ-rays. The nuclear absorption of a neutron results in the release of a substantial amount of energy (~7 MeV), usually in the form of a high-energy photon; this release complicates the development of effective shielding to attenuate neutrons.[1] Hence, complex designs for shielding are necessary to attenuate both neutrons and γ-rays.

EXPOSURE

Radiation from natural sources has existed on earth since the beginning of evolution; the three main sources of natural radiation are: 1) internal radiation from potassium-40 and other natural radionuclides, 2) terrestrial radiation from radium and other radioactive elements in the earth's crust, and 3) cosmic radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

originating in outer space. The importance of radiation during our evolution is unclear.[4] Radiation from human sources is new to our environment, including medical irradiation, low-level radioactive waste from nuclear reactors and medical applications, flying at high altitude, and fallout from nuclear testing and nuclear incidents (i.e., accidental and intentional releases). The biological effects of human and natural radiation sources are similar, depending on the cumulative absorbed dose. Minor sources of artificial radiation include nontobacco consumer products (e.g., color television sets, luminescent material, smoke detectors), nuclear power production, fallout from nuclear weapons testing, and radionuclides in the minerals of building materials and phosphate fertilizers exclusive of radon. These sources produce exposure pathways involving either *direct exposure* to ionizing radiation during and immediately after the release (e.g., nuclear detonation, medical irradiation) or continuing internal and external *radioactive contamination* from deposition of radionuclides. The former pathway includes primarily high-energy photons (γ- and X-rays) and/or neutrons, whereas radionuclides typically emit high-energy α-particles, β-particles, and/or photons (γ-rays, X-rays). Persons with direct exposure to ionizing radiation are not radioactive and do not represent a hazard to other people; however, people contaminated by radionuclides continue to expose themselves and adjacent people to continuing ionizing radiation until the completion of decontamination.

Background Radiation

In France, the United States, and the United Kingdom, the natural radiation dose in different regions, including radon, ranges from ~1.5–6 mSv.[5] The estimated US annual per-capita effective radiation dose from natural and human sources increased from 3.0 mSv in 1980 to 5.6 mSv in 2006.[6] The recent increase in medical radiation results primarily from the increased use of CT scanning, particularly in patients receiving relatively high annual radiation doses (>20 mSv). The actual effective absorbed dose received by a particular individual depends on their lifestyle and geographic location. Skiing or climbing far above sea level increases the natural radiation dose 2–3 fold compared with similar activities at sea level.[7] Natural radiation doses in certain geographic locations (e.g., Kerala, India; Brazil) may exceed US exposures 10–100 fold;[8] the difference results primarily from radon exposure.

For the average individual in the United States, radiation from occupational exposure, nuclear power production, and miscellaneous environmental sources including nuclear fallout contributes negligible amounts to their overall radiation exposure. Radiation exposure during adulthood limits the biological effects of human sources compared with the lifetime radiation exposure from natural radiation.[9] Although *low* doses of natural radiation are not conclusively linked to elevated cancer rates, this type of exposure produces biological effects (e.g., increased frequency of chromosomal aberrations in lymphocytes).[10,11]

Consumer products account for relatively small amounts of radiation. The major source of population exposure to X-rays from television was color television receivers manufactured before 1970; current estimates of the average annual effective dose are <5 μSv/year.[12,13] The emission of X-rays from color television sets and video display terminals was below the limit of detection for many instruments. The estimated average annual effective dose for X-ray emission from airport luggage inspection systems is <0.01 μSv; most personnel scanning systems use magnetic metal detectors and nonionizing radiofrequency radiation rather than ionizing radiation.[12,14] In a study of stray radiation from baggage X-ray equipment, none of the surveyed equipment presented a health hazard to the public or operators; the annual dose equivalent for workers near this equipment was below the occupational limit of 5 mSv.[15] In a study of a Taiwan airport using dosimeters, the calculated annual effective radiation doses were as follows: 1) export conveyor, 0.12 mSv; 2) outward face of X-ray scanning chamber, 0.39 mSv; and 3) X-ray image monitor, 0.16 mSv.[16] The estimated mean effective dose using tissue-weighting factors of the International Commission on Radiological Protection (ICRP) for a 10-year-old child using a phantom was 3.39 ± 0.33 μSv/scan.

Table 39.2 lists examples of the approximate effective radiation dose from external radiation and medical

TABLE 39.2. Comparison of radiation exposures. The values in the tables are approximations used only to compare different types of ionizing radiation exposures. The actual value of the individual exposures listed varies depending on several factors.

Exposure	Effective Dose (mSv)
Transatlantic flight	0.08
Diagnostic chest X-ray	0.1–0.2
Annual background radiation	3–6
Barium study	6
Cardiac angiography	8–10
Mild acute radiation sickness	2,000
Acute LD_{50} for single radiation dose	4,500

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

procedures compared with the radiation dose required to produce radiation sickness.

Radiation Incidents

Classifications of significant radiation accidents include: 1) whole body dose ≥0.25 Sv, 2) skin dose ≥6 Sv, 3) external radiation absorbed dose ≥0.75 Sv, or 4) internal contamination ≥½ the maximum permissible body burden as defined by the International Commission on Radiological Protection.[17] Funded by the US Department of Energy, the Radiation Emergency Assistance Center/Training Site Registry of Oak Ridge Associates Universities in Oak Ridge, Tennessee, maintains a list of significant radiation injuries; the data indicate ~20 significant radiation accidents occur annually with ~5 fatalities, primarily as a result of total body irradiation. Except for the Chernobyl accident, radiation devices accounted for most fatalities. These latter accidents usually involve unsuspected exposure to radioactive sources from radiotherapy machines. Overexposure to radiation also occurs due to operator error or failure of the radiation device.

Conceptually, radiation accidents include the following three categories: 1) external, 2) internal or external contamination, and 3) a combination of an external source plus contamination with a radionuclide. External radiation results from exposure to an external radiation source (e.g., X-ray machine, particle accelerator, radioactive material). These accident types do not involve direct contact between the patient and the radiation source; hence, the radiation exposure ceases when the person leaves the radiation source (e.g., γ- or X-rays). Contamination occurs following the release of radioactive dust, gases, or liquids that deposit radioactive *dirt* either externally on the skin or internally (e.g., open wound, lungs, gastrointestinal tract, or urinary tract). A contaminated patient remains radioactive until the radioactive material physically decays or the body eliminates the radioactive material (e.g., radionuclide). Consequently, the excretions and lavage fluids from contaminated patients pose a radiation hazard.

Increasing public concern exists over nuclear terrorism from an attack on a nuclear power facility or the intentional/unintentional use of a nuclear weapon. Besides unintended radiological/nuclear accidents, potential radiation incidents involving the deliberate detonation of radioactive material include: 1) deliberate destruction of nuclear power facilities (Israel's 1981 attack on Iraq's Osirak nuclear power facility, Hamas' 2014 targeting of Israel's Dimona nuclear power plant); 2) detonation of radiological exposure devices by terrorists including a nuclear bomb or sophisticated nuclear weapon; 3) release of radioactive material in a conventional explosive device ("dirty bomb"); and 4) detonation of an improvised nuclear device stolen from a nuclear facility.[18]

Explosions

Nuclear explosions produce the following types of energy (percentage of total energy): 1) heat (~35%), 2) shock or bomb blast (~50%), and 3) radiation (~15%). Heat and intense light cause flash, flame, retinal burns, and flash blindness from temporary depletion of retinal pigment, whereas blast waves cause fractures, lacerations of internal organs, pulmonary hemorrhage, and acute respiratory distress syndrome.

Hiroshima and Nagasaki

On August 6, 1945, a unique uranium gun-type atomic (fission) bomb ("Little Boy") exploded with a force of ~15 ± 4 kilotons of TNT (trinitrotoluene) 576 m above the city of Hiroshima, virtually destroying all buildings in a 5-square mile area. Civilian causalities included 78,150 dead, 13,983 missing, and 37,424 injured.[19] Three days later, a ~22 ± 2 kiloton plutonium implosive device ("Fat Man") detonated 507 m above Nagasaki. Total civilian causalities exceeded 49,000 with few survivors within 1 km of the hypocenters; most of the deaths resulted from projectiles, percussive forces, and thermal injuries rather than radiation injuries; <10% of the energy released by the bomb formed ionizing radiation, primarily neutrons and γ-rays. A study of the effects of the bomb blast on the Japanese population confirmed that most of the initial deaths resulted from the immediate effects of thermal burns and trauma secondary to blast injuries.[20] The estimated intensity of the heat ranged from 3,000–4,000°C at the hypocenter to 573°C at distances of 1,000–1,600 m from the hypocenter. All persons within 4 km of the hypocenter without shielding suffered some degree of burns.[20] Additional injuries resulted from the compression and suction phases of the blast that reached up to 6–8 tons/m^2. An estimated 5% of cancer deaths among A-bomb survivors resulted from radiation exposure after the atomic bomb explosions in Hiroshima and Nagasaki, based on 63 years of follow-up.[21]

The 1950 Japanese National Census estimated that these two atomic bombs exposed ~280,000 persons directly to ionizing radiation. The Hiroshima weapon was a unique bomb that fired one block of uranium-235 into a gun assembly composed of steel. The Nagasaki weapon imploded a shell of plutonium-239 into a shell of depleted uranium-235. Although differences in the

construction of the bombs initially were thought to result in greater exposure to neutron radiation at Hiroshima than Nagasaki, reevaluation of dosimetry at Hiroshima (DS86) decreased the neutron radiation dose to 10% of the T65DR estimates.[22] The current estimates of neutron radiation are too small to predict accurate estimates of the relative biological effectiveness of neutron radiation from that data.[23] In contrast to the unique detonation of the bomb at Hiroshima, the bomb type used at Nagasaki was tested several times in the Nevada Desert.

Initial Radiation For >90% of the survivors, the radiation dose was <0.01 Gy (10 rads) with a range up to ~3 Gy.[19] The estimated mean lethal dose of whole-body radiation required to kill 50% of humans within 60 days is 3.25–4 Gy without supportive care and 6–7 Gy with intensive supportive care.[24] In comparison to this dose, an increased incidence of malignancy generally occurs after exposure to radiation doses ~30 times higher (i.e., >0.3 Gy) than the radiation dose of most survivors.[25] Within the fireball above the cities, there was a dynamic mass of fission products that emitted delayed radiation from neutrons and γ-rays. Prompt radiation from high-energy γ-rays produced by neutrons from fission reactions ≤1 second after the nuclear explosion preceded the bomb-induced shock wave.[22] The survivors were exposed to radiation from the air proportional to the amount of shielding material, radiation scattered from the earth, and radiation reflected from buildings, depending on their orientation to these sources. An in-air tissue absorbed dose for γ-rays was estimated from thermoluminescent bricks and tiles of these cities; for neutrons, estimates were based on radiation-induced radioactivity of ^{60}Co in iron reinforcement bars within concrete buildings.[26]

President Harry Truman approved a directive to the National Academy of Sciences/National Research Council to undertake a long-range, continuous study of the biological and medical effects of the atomic bomb. In 1947, the Atomic Bomb Causality Commission (ABCC) was formed to study Japanese survivors; this organization was restructured in 1975 to the Radiation Effects Research Foundation (RERF). Early observations detected cataracts, leukemia, and birth defects, resulting in an initial focus on the blood, growth and development, and ocular effects. In 1955, the Francis Committee developed a unified study program to follow mortality and cancer incidence in a fixed sample of ~120,000 atomic bomb survivors and control subjects (Life Span Study). This cohort included ~1/2 of all survivors with high radiation exposure alive 5 years after the bombing.[21] Over 60% of these survivors received radiation doses of <100 mGy. Later, cohorts of survivors exposed *in utero* (*in utero* cohort) and children of exposed and nonexposed parents (F_1 cohort) were added. Although there were no direct measurements of radiation from the two bombs, calculations of individual radiation doses (γ-rays, neutrons) were calculated from the distance from the hypocenter, external shielding (terrain, buildings), and body self-shielding corrected for orientation, position of the organ doses, and age. The ABCC initially released estimates of radiation-related risks of cancer among Japanese survivors of the atomic bomb blasts based on their estimates (Tentative 1965 Dose Revised, T65DR) of the radiation dose. No risk estimates were available for cohort data from 1945–1950. After a reassessment of the individual doses by Japanese and American scientists, the individual doses were revised in the Dosimetry System 1986 (DS86). The DS86 system reduced some but not all biological ambiguities (i.e., epilation data, somatic mutations, cytogenetic abnormalities) present in the previous systems. The current dosimetry system (DS02) includes estimated radiation doses for 15 organs.[27] Some survivors in the Life Span Study received whole-body radiation doses approaching lethality (i.e., >2 Gy); however, the mean whole-body radiation dose for survivors receiving >0.005 Gy was ~0.2 Gy.[21] Although the cancer mortality data per absorbed dose is still higher in Hiroshima than Nagasaki, the difference is no longer statistically significant.[28]

The three different forms of estimating the dose of an individual include: 1) free-in-air kerma, 2) the shielded kerma, and 3) the organ-absorbed dose. The free-in-air kerma is the kinetic energy released at a point in air over bare ground, whereas the organ-absorbed dose is the radiation absorbed by a specific organ. The shielded kerma is the dose delivered to the skin of an individual; this value adjusts the free-in-air KERMA for the shielding of building structures. The DS86 data reduce the shielded KERMA dose somewhat, and risk estimates using the new shielded KERMA data are 40% higher; however, the DS86 organ dose and risk estimates based on that data do not differ significantly from the T65DR estimates.[29,30]

Figure 39.1 demonstrates the free-in-air absorbed doses adjusted for shielding of the houses (i.e., shielded kerma) and distance from the hypocenter. The hypocenter is the location on the ground vertically below the epicenter (i.e., the point in the air where the atomic bomb detonated). The actual absorbed dose equivalent required to calculate risk must be adjusted by the experimentally derived *R*atio of the in-*A*ir *T*issue dose to the *A*bsorbed dose (RATA) in critical organs based on the orientation of the individual to the hypocenter. This value converts the shielded KERMA into an average organ-absorbed dose.

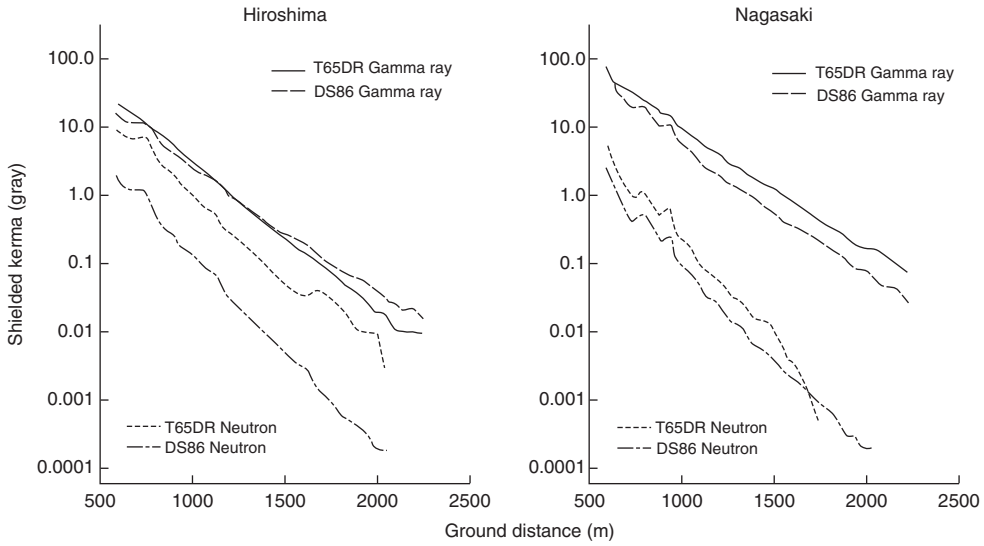

FIGURE 39.1. Shielded kerma (Gy) by city, ground distance from the hypocenter, and dosimetry system. (Shimizu).[29]

Fallout Atomic bomb-induced radioactivity and radioactive fallout from these two atomic bombs were additional sources of radiation exposure for the survivors. These radiation sources were the primary sources of radiation exposure for the early workers entering the bombed areas and the residents of areas receiving only fallout.[31] The radioactive fallout was deposited by yellow-brown clouds at a distance that minimized exposure to neutron radiation. The radioactive fallout was called black rain. This source dominated the radiation exposure in areas including the Nishiyama district near Nagasaki, where the inhabitants were shielded from the atomic blast by Mt. Kompira. The Nishiyama district received most of the fallout from the atomic bomb that exploded over Nagasaki. Although the average dose secondary to external radiation from fallout averaged ~0.3–1.3 Gy (30–130 rads), the only clinical abnormality detected was leukocytosis 2 months following the explosion.[32] Increased ^{137}Cs in the soil and agricultural products accounted for most of the internal radiation dose. These inhabitants did not develop thyroid nodules or thyroid malignancies as the Marshallese of Bikini did when large amounts of neutron-activated ^{131}I in coral debris produced much higher internal radiation doses.[33] In 1969, the average residual dose of external radiation for males and females in Nagasaki was 2.9 μGy (0.29 mrad) and 1.9 μGy (0.19 mrad), respectively.[32] These levels were ~500 times lower than the maximum annual dose limit recommended by the International Commission of Radiological Protection (ICRP) at that time.

Unfortunately, the exact compositions of fission products from the explosion were not directly measured. Based on experimental irradiation of soil from Hiroshima and Nagasaki, the following five radioactive species (half-lives) were most abundant: ^{28}Al (2.3 minutes), ^{56}Mn (2.58 hours), ^{24}Na (15 hours), ^{46}Sc (84 days), and ^{60}Co (5.3 years). Immediately following the detonation of the atomic bombs, the external dose rate primarily resulted from ^{56}Mn (0.94 rads/hour) and ^{24}Na (0.92 rads/hour); however, by 10–15 days post-explosion, the main source of radiation was ^{46}Sc.[31] The estimated cumulative radiation dose from the fallout in Hiroshima calculated over a lifetime was 0.13 Gy (13 rads).

Induced Radioactivity The cumulative radiation dose from soil activated by neutrons and γ-radiation for a person present at the hypocenter and residing there permanently was ~0.8 Gy (80 rads) in Hiroshima compared with ~0.3 Gy (30 rads) in Nagasaki.[26] At 500 and 1000 m from the hypocenter, the radiation dose decreased to 18% and 0.07% of the value at the hypocenter, respectively. These estimations did not consider the following: 1) β-radiation, 2) fallout of fission products, 3) internal doses from inhaled or ingested radionuclides, and 4) shielding.

Weapons

Hypothetical Attacks

Detonation of a nuclear weapon creates the following phenomena that contribute to physiological effects in humans and animals: 1) thermal wave, 2) blast wave, 3) initial γ- and neutron radiation, 4) radioactive fallout, 5) atmospheric disturbances, and 6) electromagnetic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. pulse.[34] A nuclear explosion produces over 200 radionuclides that possess different yields and half-lives as well as different physical and biological characteristics.[35] Individuals receive an **external** dose from the radioactive fallout passing overhead (cloud shine) and the ionizing radiation (neutrons, γ-rays). For most survivors, most of the external dose results from the deposition of radionuclides on the surface. The **internal** dose of radiation results primarily from the ingestion of radioactive material in food and water. Computer models indicate inhalation of radionuclides does not contribute significant amounts of radiation compared with the external dose except for ^{131}I irradiation of the thyroid.[35] These models also predict that the average American family surviving a nuclear explosion in their home would receive an internal dose that represents ~2% (0–0.17 Sv) from ingestion compared with a 48-hour external dose of 0.15–4.6 Sv over 48 hours postexplosion.

Based on nuclear testing at the Nevada Test Site, the most important radionuclides comprising the internal radiation dose are ^{137}Cs and ^{90}Sr with lesser contribution from ^{131}I and ^{89}Sr.[36] Although prediction of a radiation dose of a particular individual during a major nuclear attack is difficult, models (e.g., PATHWAY for calculation of time dependent ingestion) are available to estimate the average internal dose in certain locations given certain assumptions. These variables include the availability of food and water, actual nuclear war scenario, fallout pattern, climatic conditions, shielding from radiation, and transportation. These models can predict the internal dose from multiple explosions over a short period of time or fallout derived from prior nuclear explosions.

Weapons Testing

Between 1945 and 1980, >500 nuclear tests were conducted that released radioactive debris into the atmosphere. The deposition of nuclear debris was less in the Southern Hemisphere than in the Northern Hemisphere where the tests occurred. Nuclear testing began in the Pacific at Bikini atoll and continued until 1958. The large-scale atmospheric testing of nuclear devices occurred primarily between 1952–1958 and 1961–1962 (Christmas Island, Johnson Island). These nuclear explosions carried radioactive materials into the stratosphere where the mean retention time was ~1–5 years.[37] Deposition of radioactive debris was doubled in the mid-latitudes compared with the equator and polar regions as a result of the preferential air exchange between the stratosphere and troposphere in the mid-latitudes and air circulation in the troposphere.[38] Table 39.3 displays the yields of atmospheric nuclear testing from 1945–1980 in millions of tons (megatons) released into the atmosphere. In 1963, the annual average effective dose rate from atmospheric nuclear testing peaked in the Northern Hemisphere at 125 μSv, whereas the dose rate in the Southern Hemisphere peaked at 59 μSv in 1962.[39]

TABLE 39.3. Nuclear fission and fusion yields in megatons (Mt) from atmospheric nuclear tests by 5-year intervals, 1945–1980. (Modified from UNSCEAR).[38]

Interval	Tests	Fission Yield	Fusion Yield	Total Yield
1945–1950	9	0.2	0.0	0.2
1951–1955	83	39.0	23.7	62.7
1956–1960	172	41.8	46.6	89.4
1961–1965	179	90.2	166.8	257.0
1966–1970	29	12.3	8.4	20.7
1971–1975	25	3.1	2.2	5.3
1976–1980	7	2.9	1.9	4.8

In 1954, misjudgments in weather patterns and bomb yield resulted in the exposure of the residents of Rongelap, Ailinginae, and Utirik atolls in the Northern Marshall Islands to radioactive iodides. The estimated external γ-doses in air for evacuated inhabitants of Rongelap, Ailinginae, and Utirik were 1.9 Sv, 1.1 Sv, and 0.11 Sv, respectively, whereas the estimated mean doses of whole body external γ-radiation were ~10% of the external γ-doses in air.[40] Epidemiological data indicate that the highest radiation doses produced adenomatous thyroid nodules in the Rongelap inhabitants. In a study of 168 of the 253 exposed inhabitants ~40 years after the incident, no significant differences were found in the incidence of thyroid nodules or the mean nodule count between the three groups of exposed residents in Rongelap and Utirik and a comparison patient population.[41] Papillary thyroid carcinoma is the most common histological type of sporadic and radiation-associated thyroid cancer; this type of cancer is relatively benign. To date, there has been no mortality in the Marshallese population associated with the 1954 incident.

The fallout from nuclear explosions results in exposure to internal radiation from the ingestion of radionuclides incorporated in food and external radiation from radionuclides deposited on the ground. Epidemiological studies of radiation exposure in inhabitants near the Nevada Test Site have not detected definite evidence of excess cancer risks from fallout exposures; however, risk estimates do not exclude small increases in leukemia and thyroid cancer risks.[42] From 1962–1980, comparatively smaller nuclear weapons testing transported radioactive material only into the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. troposphere; radioactive fallout occurred over days to weeks. Atmospheric testing of nuclear weapons ceased in 1980. Underground testing of nuclear devices generally causes few serious effects on the environment.[37]

Long-lived radionuclides (strontium-90, carbon-14, cesium-137) produce the greatest exposure to ionizing radiation following large atmospheric nuclear tests, whereas γ-emitting radionuclides (ruthenium-106, zirconium-95) are important sources of ground contamination following nuclear explosions in the troposphere. The 1977 UNSCEAR Report estimated the collective dose commitment from nuclear explosions before 1976 at ~800–1,600 million man rad including carbon-14 exposure.[43] At that time, the estimated exposure from natural sources of radiation (~300 million man rad) exceeded the radiation dose from fallout by three to five times; hence, the collective effective dose equivalent commitment from all nuclear testing in the atmosphere is similar to the amount of radiation received by the population from natural sources over 3 years. Consequently, the increased risk of cancer from fallout for the general population is relatively small compared with the underlying cancer risk in the absence of exposure to fallout near the site of detonation.

Radiological Dispersal Devices (RDDs)

RDDs refer to any device used for intentional dissemination of radioactive material without a nuclear detonation. These "dirty bombs" potentially produce radioactive material (dust, shrapnel), distribution of radioactive contamination, blast injury (burns, blunt trauma, penetrating wounds), and panic; however, mass causalities associated with nuclear explosions usually do not occur. Following the detonation of a RDD, most fatalities and injuries would probably result from the trauma associated with the explosion depending on the dispersion pattern, type/quantity of radioactive material released, and device design.[44] Although some persons close to the explosion may require decontamination from external and, less commonly, internal contamination, the contamination level does not usually produce the severe radiation exposure necessary to require medical intervention.[45] Potential radioactive isotopes contained in RDDs include ^{137}cesium, ^{241}americium, ^{60}cobalt, and ^{192}iridium, with ^{252}californium, ^{238}plutonium, ^{210}polonium, ^{226}radium, and ^{90}strontium being much less common.

Power Plants

Production

The nuclear fuel cycle includes: 1) mining and milling, 2) enrichment and fabrication, 3) reactor operation, and 4) reprocessing. The transportation of nuclear material and disposal of waste also represent potential sources of radiation exposure. Although the concentration of radionuclides in effluent is small, some radioactive material is released into the environment at each step. Fuel fabrication and transportation of nuclear fuel usually produce little radiation exposure. Overall, recent environmental monitoring suggests the normalized collective effective dose equivalent commitment for radionuclides in the effluents of nuclear fuel cycle installations is ~4 man-sievert (S)/gigawatt (GW) of electricity produced.[37] The man-sievert is a calculated measure designed to optimized radiological protection with units of J/kg. Based on the current annual nuclear production of 190 GW/year, the annual per caput dose estimate is 0.15 μSv; this value represents ~0.01% of the annual dose from background radiation.

Plant Accidents

Accidents involving the release of radiation may occur at any point in the nuclear fuel cycle, including transportation and processing phases. Additionally, these accidents may be associated with the release of hazardous materials (e.g., hydrogen fluoride, sulfuric acid, chlorine, ammonia, sodium hydroxide, hydrazine). Most accidents at a nuclear power plant involve trauma (superheated steam burns, crush injuries, electrical injuries, blunt trauma from falls, heat illness) rather than significant radiation exposure. Accidental radiation exposure most often occurs during outages (e.g., during refueling) when there is inadequate shielding between a worker and a reactor, an activated metal, or spent fuel rods.

Large-scale nuclear accidents occur when enough fissionable materials (uranium-235, plutonium-239) meet in an environment containing a large neutron flux. Then a nuclear reaction develops, and the core material becomes *critical*. The intense heat from this *criticality* accident causes the fuel rod assemblies to melt and the reactor to explode from excessive steam pressure. A nuclear explosion does **NOT** happen because the reactor fuel contains only 3% ^{235}U in contrast to nuclear bombs that contain up to 90% ^{235}U.

Nuclear power plants contain large quantities of radionuclides; the potential for serious radioactive contamination of the environment exists when the superheated steam is released from the reactor core. The potential health consequences of such a release depend on the characteristics of the individual radionuclides (e.g., chemical and physical properties, biological behavior in the food chain, physical and biological half-lives, decay form). Important radionuclides released from such an environment include: 1) krypton and xenon

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

gases (primarily external radiation because of half-lives in hours except the ~11-year half-life of ^{85}Kr), 2) potential release of large amounts of volatile ^{131}I, 3) minimal internal hazard of tritium resulting from a 10-day half-life, 4) ^{137}Cs (a potassium analog with a 30-year half-life), and 5) ^{90}Sr (nonvolatile calcium analog that accumulates in bone with a half-life of several years).

Windscale-1, United Kingdom From a health perspective, ^{131}I was the most important radionuclide released during the fire at the Windscale reactor in the UK on October 10, 1957, especially in the contamination of infant milk.[46] The physical half-life of ^{131}I is ~8 days; however, this isotope is rapidly absorbed and concentrated in the thyroid. The absorbed dose from ingestion of radionuclides (e.g., ^{137}Cs, ^{131}I, ^{89}Sr, ^{90}Sr) far exceeded the dose inhaled from these radionuclides. The age-corrected collective effective dose equivalent for the British population was ~1,200 man-sievert.[47] Risk estimates suggested up to 30 excess cancer deaths resulted from the environmental contamination, with ~½ resulting from ^{210}Po exposure.[48]

Three Mile Island-Unit 2, United States The Three Mile Island plant contains two pressurized water reactors. Figure 39.2 is a schematic diagram of one of these units. Although the actual release of radioactivity from this plant was minimal, the accident dramatized the possibility that enormous amounts of heat and radioactivity could be released from nuclear reactors following a major loss of reactor coolant. At 4 a.m. on March 10, 1979, a slow reactor coolant leak began from the pressurizer within the containment building. Contributing to the accident were the block valves that carried auxiliary feed water to the steam generator. Inadvertently, these valves were closed, resulting in a blockage in the transfer line and the failure of the condensate pumps. The lack of heat removal by the secondary loop dramatically increased the temperature and pressure of the reactor. As designed, the reactor shut down within 1 second and no nuclear explosion occurred; however, the inability of the operators to control continuing heat formation by the decay of fission products led to the accident.

Unknown to the operators, the pilot-operated relief valve stuck open and water continued to pour out of the primary coolant system, ultimately causing spillage of radioactive coolant onto the floor of the containment vessel. Because vibrations developed in the primary coolant pumps, the operators decided to shut off the circulation pumps rather than allow an automatic increase in the amount of water in the coolant system through the high-pressure injection system. These operators mistakenly believed high water levels in the pressurizer meant the primary loop was filled with coolant. In fact, the primary loop contained radioactive, superheated steam. Consequently, the core overheated and steam voids developed throughout the system. Approximately 10 hours after the accident began, a hydrogen explosion occurred in the containment building; however, no explosion ever occurred in the nuclear reactor. Release of radioactive iodine and noble gases followed the inadvertent pumping of radioactive coolant from the floor of the containment building to an auxiliary building.

Exposure Only noble gases and a limited amount of radioactive iodine escaped from the containment building.[49] Up to 3.7×10^{17} Bq (10 MCi) of the radioactive noble gases were released into the environment. The major noble gas was ^{133}xenon (half-life of 5.3 days) and to a lesser extent ^{135}xenon (half-life of 9.2 hours). Approximately 2.6×10^{15} Bq (10 KCi) of ^{131}I escaped from the core; that amount represented ~0.01% of the total amount of ^{131}I in the reactor core.

Dose The highest radiation dose measured outside the containment building was 10.2 mSv.[50] Based on field dosimetry, the Ad Hoc Inter-Agency Dose Assessment Group from the Nuclear Regulatory Commission, the Department of Health, Education, and Welfare, and the Environmental Protection Agency estimated the average collective dose for the population within 50 miles to be 33 man-sievert (3,300 person-rem).[51] The estimated average likely and average maximum whole-body γ-radiation doses for individuals living within 5 miles of the plant were 0.09 mSv (9 mrem) and 0.25 mSv (25 mrem), respectively. These values represent a fraction of the yearly dose received by persons in the United States from natural background radiation.[52] The maximum dose to an individual near the plant assuming no shelter was 0.83 mSv (83 mrem).[50] The population surrounding the plant received no significant internal dose from the ingestion or inhalation of radionuclides released into the environment.[53]

Health Consequences Conservative estimates of the cancer risk from the radioactive gases based on a linear, no-threshold model suggest few adverse reactions would occur.[54] The task force of the President's Commission estimated 0.7 excess cancer deaths with a 50% probability that no deaths would occur.[53] These risk estimates indicate the resulting deaths from this type of radiation exposure could not be detected in an epidemiology study of the exposed population. Increased cancer incidences in the TMI cohort are generally small and nonsignificant statistically. A cancer incident study for the period 1975–1985 did not detect any definite effects

of exposure to the 1979 accident when analyzing the cancer types and population subgroups most susceptible to radiation.[55] Odds ratios for childhood cancers and childhood leukemia demonstrated no clear evidence of statistically significant increases in cancer risks. The confidence intervals were wide with no dose-response relationship between radiation exposure and cancer incidence. A retrospective cross-sectional study of records from 26,357 thyroid cancer patients and 2,611 patients within the Three Mile Island (TMI) area using data from the Pennsylvania Cancer Registry 1985–2008 demonstrated a higher proportion of papillary thyroid cancer ($P < 0.001$) and a lower proportion of follicular thyroid cancer ($P < 0.001$) in the TMI area population.[56] However, the incidence of thyroid cancer in the TMI group was not statistically different from the rest of the state. Using the same data, the risk of all malignant neoplasms was similar (RR = 1.00, 95% CI: 0.97–1.01) between the TMI cohort exposed to higher maximum radiation and the rest of the cohort after adjusting for age, gender, education, smoking, and background radiation.[57] In the higher exposure group, the leukemia risk in men (RR = 1.15, 95% CI: 1.04–1.29) but not women was elevated.

Chernobyl-Unit 4, Ukraine The world's most serious accident at a nuclear power plant occurred at Unit 4 of the Chernobyl nuclear power plant in Ukraine on April 26, 1986. Plant operators were performing a low-power engineering test without appropriate safety system operations when they lost control of the reactor. The subsequent steam explosion blew the 1,000-ton cover off the top of the reactor, and the hot, highly radioactive pieces of the reactor core started fires in nearby buildings. The design of the reactor at Chernobyl was a boiling-water, graphite-moderated reactor that was not in current operation outside the Soviet Union. The reactor had a positive void coefficient at low power that results in multiplication of both neutrons and power following water loss. Furthermore, the containment building provided much less protection than other types of reactor designs.[58] As a result of numerous violations of operating procedures listed in Table 39.4, a prompt critical reactivity excursion occurred that melted the uranium oxide leading to a steam explosion.

This explosion blew off the roof and released ~3–5% of the fission products in the nuclear reactor core as well as all of the noble gases and ~40–60% of the volatile nuclides.[59] The release of radioactive material from the Chernobyl reactor was ~200 times greater than the combined radioactivity released from the two atomic bombs dropped on Nagasaki and Hiroshima.[60]

The explosion and resulting fire vaporized the reactor core and destroyed parts of the reactor turbine buildings. A radioactive plume rose 10 km above Chernobyl. Over the next 10 days, 5,000 tons of material including boron carbide, dolomite, clay-sand mixtures, and molten lead were dropped without successfully suppressing the fire. Finally, the injection of liquid nitrogen into the passages below the reactor core cooled the reactor sufficiently to stop the evaporation of fission products.[1] Twenty-five percent of the release of radioactive material occurred instantaneously, with the rest of the release spreading over the 10-day period before the fires were extinguished.[2] The amount of radioactivity released over the 10 days required to extinguish the graphite fires exceeded previous releases from reactor accidents by several orders of magnitude.

Exposure The explosion and subsequent fire released primarily short-lived radioiodine and long-lived radionuclides including 1,760 petabecquerel (10^{15} Bq) ^{131}I, 85 PBq ^{137}Cs, and 35 PBq ^{134}Cs, along with similar amounts of noble gases as a plume traveling into adjacent parts of Russia, north into Belarus, west into Ukraine, and, to a lesser extent, over Europe and the Northern Hemisphere (e.g., Finland, Norway, Sweden, Austria, Bulgaria).[61,62] The Chernobyl nuclear power plant was

TABLE 39.4. Operator procedure violations during the Chernobyl-4 nuclear power plant incident. (Royal).[50]

Violation	Consequence
Power level below specified procedures	Large positive void reactivity coefficient, resulting in difficulty controlling reactor and overall positive power coefficient
Improperly positioned control rods	Unauthorized configuration resulted in ineffective emergency protective system
Authorized levels of coolant flow exceeded by operating all eight main circulation pumps	Reduced voiding with coolant temperature near saturation
Reactor scram signal blocked from loss of both turbine generators	Lost automatic scram protection at the start of ill-fated test
Reactor scram on water level and steam pressure in the drum separator was blocked	Lost reactor protection system based on thermal parameters
Emergency core cooling system turned off	Lost ability to reduce severity of the accident

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. located 10 km south of the border with Belarus. The release lasted ~2 weeks (April 26, 1986–October 5, 1986) with highly variable aerosol characteristics and meteorological conditions causing extremely heterogeneous contamination of the surrounding areas. The most heavily contaminated areas were in Belarus, the Russian Federation, and Ukraine. Initially, the exposure to ionizing radiation consisted primarily of ^{131}I, whereas contamination during later phases resulted mainly from ^{137}Cs, ^{134}Cs, and ^{90}Sr.

For the patients hospitalized with acute radiation syndrome, the primary sources of radiation were external whole-body γ-radiation and extensive high-energy β-radiation to the skin. Contamination by radionuclides did not contribute significantly to the high radiation doses received by these hospitalized patients.[63] Many of the emergency personnel sustained extensive β-irradiation to the skin when highly contaminated water penetrated the porous canvas material of their protective clothing. Sodium-24 analysis indicated neutron exposure was minimal, and lung radionuclide surveys indicated internal contamination did not contribute significantly to the total radiation dose except in two cases.[64]

The initial evacuation of 45,000 people from Pripyat, located 2–4 km from the Chernobyl reactor, was delayed up to 36 hours to select the safest escape route, assemble buses, and reduce radioactive dust by spraying polymers on the ground surfaces.[2] Keeping people indoors during the initial 24 hours when most of the radioactivity was released also reduced their radiation exposure. Winds and rainfall governed the spread of the radioactive material; the deposition of radionuclides was heterogeneous. High radionuclide concentrations were deposited by rainfall in the area near the Chernobyl reactor.

An additional 70,000–90,000 people living within 30 km of Chernobyl were evacuated during the first 2 weeks when the graphite fires continued to release a radioactive plume. The initial cause of radiation exposure for the population surrounding Chernobyl during 1986 was the many short-lived radionuclides consisting primarily of ^{131}Iodine (8 day half-life) and to a lesser extent ^{132}I, ^{103}Ru, ^{95}Nb, and ^{95}Zr.[65,66] In the regions near Chernobyl that were not evacuated, the amount of internal radiation (inhalation of radionuclides from the radioactive plume, ingestion of contaminated food or water) was approximately equal to the amount of external radiation (radioactivity from the plume and fallout).[67] However, most of the short-lived radionuclides decayed by 1987 and the vast majority (>70–99%) of the subsequent radiation exposure resulted from the dispersion of ~70 PBq of long-lived ^{137}Ce with a half-life of ~30 years. This amount of ^{137}Cs corresponds to 22 kg spread mostly across the Northern European Hemisphere.[68] Cesium deposits on plants and enters vegetation through the roots. Rich sources of ^{137}Cs included meat, milk, potatoes, mushrooms, and berries.

DOSE Acute radiation sickness developed only among the reactor staff and firefighters. Eight medical attendants on the scene developed acute radiation sickness including one physician who later died. Because most environmental monitors were destroyed and most personal dosimeters were inadequately designed to detect high doses of radiation, estimation of the actual radiation dose depended on biological dosimetry including onset of vomiting, blood lymphocyte count, and the analysis of the distribution of cytogenic abnormalities. More than 100 workers received an estimated radiation dose of >1 Sv and the 20 most heavily exposed workers received 6–16 Sv (i.e., substantially >50% lethal dose of 4.5 Sv).[69] Because of the magnitude of the accident, complete decontamination on the scene was impossible; therefore, cleanup personnel received some irradiation. The average estimate of the radiation dose received by the cleanup personnel during the first 3 months after the explosion was ~300 mGy based on limited biological dosimetry. The overall average yearly estimated dose for these workers based on information from the Russian Obninsk Registry was 170 mGy in 1986, 130 mGy in 1987, 30 mGy in 1988, and 15 mGy in 1990.[70]

From the standpoint of individual risk, the radiation dose received outside the region of Chernobyl was not significant except for the average dose of external radiation for people living 3–15 km from Chernobyl (0.35–0.55 Sv), whereas the remaining evacuees received a dose of ~0.03–0.06 Sv.[71] The estimated collective effective dose equivalent commitment was ~600,000 man-sievert (S) divided between the USSR (40%) and the rest of Europe (57%). Countries outside the immediate area of Chernobyl (i.e., Russia, Ukraine, Belarus) receiving the largest first-year radiation doses were Bulgaria (0.76 mSv), Austria (0.67 mSv), Greece (0.59 mSv), and Romania (0.57 mSv). The North American and Southern Hemisphere countries received minimal radiation amounts from the Chernobyl accident compared with background radiation. After 1986, the radiation dose in the areas outside Chernobyl resulted almost exclusively from the deposition of long-lived radionuclides, primarily ^{137}Cs. Table 39.5 outlines the contribution of specific long-lived radionuclides to the annual external radiation dose (i.e., short-lived and long-lived radionuclides) from the Chernobyl release normalized to the unit deposition of ^{137}Cs.

The average estimated external radiation dose received by the most heavily contaminated residents of

TABLE 39.6. Estimated 50-year cumulative radiation dose from cesium isotopes released from Chernobyl as a mean value/inhabitant of all ages. (Adapted from Mole).[72]

Country	Estimated Cumulative Dose (mSv)
Bulgaria, Poland, Romania, Yugoslavia	3.5–4.2
Albania, Austria, Western Germany, Hungary, Italy, Sweden, European USSR	0.9–1.9
Turkey, rest of Europe	0.09–0.8
Asia, excluding Turkey	0.008–0.09
United States, Canada	0.004–0.005

the Ukraine from 1986–2000 was ~40 mSv.[65] Table 39.6 lists the estimated cumulative radiation dose from cesium compounds released from the Chernobyl accident in the country.[72]

Acute Health Effects The Chernobyl accident accounted for ~$^1/_3$ of reported cases of acute radiation sickness reported worldwide. About 134 of the Chernobyl workers and rescue personnel developed acute radiation sickness with 28 short-term deaths within 2 months of the disaster, primarily from bone marrow failure in plant employees and rescue workers receiving whole-body doses of >6.5 Gy.[73] One person died on the scene from trauma and another died several hours later from thermal burns. Extensive skin burns from β-irradiation occurred in 19 of these deaths. No cases of acute radiation sickness occurred in evacuated persons or the general population. Internal contamination was relatively minor clinically. Although incidences of spontaneous abortion in a Norwegian study increased from 7.2% in the 12 months before the accident to 8.3% after the accident, there was no dose-response association between adverse perinatal health effects and radiation dose based on average external radiation doses in Norwegian municipalities.[74] Additionally, studies of Norwegian municipalities did not detect any associations between radiation doses and birth defects typically associated with excessive radiation exposure (e.g., small head circumference, congenital cataracts, anencephaly, spina bifida, low birth weight).[75]

Chronic Health Effects Medically significant radiation doses for individuals were limited to the 30 km zone surrounding the Chernobyl reactor.[76] Estimates on the effect of the radiation released from Chernobyl vary widely depending on the type of model (e.g., absolute vs. relative) used to extrapolate the risk of developing cancer from high-dose exposures to the low radiation levels present in the area around Chernobyl. Instead of reporting only the upper bounds of risk estimates, recent risk evaluations included the zero-risk base commensurate with the possibility that the risk of low radiation doses may be zero.[54] Except for studies of the cohort of 25,000 people living near Chernobyl at the time of the accident, conventional epidemiological techniques are relatively insensitive to the detection of radiation-induced, excess cancer incidence (e.g., leukemia) from the current radiation exposure of the general population.

Demonstrating an increased cancer risk at relatively low annual radiation doses (5–10 mSv) requires a very large database (>100,000 person years).[77,78] Based on an average radiation dose of 0.4 Sv, this cohort may experience up to 25 additional cases (i.e., a 100% increase) in the incidence of leukemia from 1988–1998. The estimated Finnish population-weighted mean effective dose for the first 2 years post-Chernobyl was ~0.4 mSv, with the upper 20% receiving ~1 mSv.[79]

The most common malignancies associated with excessive radiation include leukemias and cancers of the thyroid, breast, and lung. No excess leukemia risk was detected in children during the first 7 years after the Chernobyl accident. In a 15-year follow-up study of 12,000 Belarusian children (median age, 7.9 years; 142,968 person-years at risk), the standardized incidence ratio (SIR) was not significantly increased statistically for nonthyroid solid cancer (SIR = 83, 95% CI: 0.61–1.11), leukemia (SIR = 1.78, 95% CI: 0.71–3.61, $n = 6$), or lymphoma (SIR = 0.66, 95% CI: 0.26–1.33, $n = 6$).[80]

The major medical consequence of the radiation released from Chernobyl is a significant increase in childhood thyroid cancer in Ukraine, Belarus, and the Bryansk region of the Russian Federation, resulting from the consumption of radioiodine-contaminated milk during May and June 1986.[81,82] By 10 years after the accident, an estimated 1,000 cases of thyroid cancer had resulted from the ingestion of the radioiodine-contaminated milk with an estimated potential of 3,000–6,000 total cases based on ecological studies.[61] By 2005, 6,448 thyroid cancers were associated with children under 18 years of age exposed to radiation from the Chernobyl incident; the majority of the cancers occurred in children <14 years of age. No significant epidemiology studies support an increased thyroid cancer risk for children born after 1986 or for adults exposed during the incident.[83]

The initial latency period appears relatively short (i.e., 4–5 years); the thyroid tumors were unusually aggressive with papillary carcinomas being the vast majority of primary tumor types.[84] However, by 20 years, the clinical course of sporadic and post-Chernobyl thyroid cancer in pediatric patients of comparable age appeared similar with an overall disease-specific mortality rate of ≤1%, despite a high recurrence rate.[85] A prospective analytical cohort study of Ukrainian residents <18 years of age at the time of the incident underwent 4 screenings from 1998–2007; the last 3 screenings detected 65 incident thyroid cancer cases.[86] The excess relative risk (ERR) model described the dose-response relationship better than the excess absolute risk model with an ERR/Gy of 1.91 (95% CI: 0.43–6.34). The ERR/Gy varied significantly with the state (oblast) of residence; the ^{131}I-related thyroid cancer risk persisted throughout the first two decades of observation. There is also a dose-related increase in hypothyroidism in the ^{131}I-exposed cohorts, primarily subclinical and antibody-negative. In a study of 10,827 Belarus residents exposed to radiation from Chernobyl as children (mean = 8.2 ± 5.0 years at exposure), the mean estimated ^{131}I dose was 0.54 ± 0.23 Gy (range, 0.001–26.6 Gy). The excess odds ratio/Gy for hypothyroidism was 0.34 (95% CI: 0.15–0.62), varying significantly with age at exposure, residency, presence of goiter, and age at examination. There was no association between antibody-positive hypothyroidism and the radiation dose.

The association between thyroid cancer in adults and radiation exposure from Chernobyl is not definitive. Consistent evidence of an increased incidence of radiation-related cancers in the Baltic cohort of Chernobyl cleanup workers has not been observed, with the possible exception of thyroid cancer. In a cohort study of 17,040 men from Estonia, Latvia, and Lithuania participating in the environmental cleanup of the Chernobyl Nuclear Power Station from 1986–1991 and followed from 1986–2007, 756 cancer cases were reported.[87] The study detected no increased proportional incidence ratios (PIR) for leukemia or radiation-related cancer sites combined. The PIR for thyroid cancers in men was elevated at 2.76 (95% CI: 1.63–4.36); however, conclusions regarding causation were limited by the effect of thyroid screening among cleanup workers. An excess of esophageal cancers was also detected (PIR = 1.52, 95% CI: 1.06–2.11). Up to 9 years after the incident, studies of cleanup workers at Chernobyl did not detect a greater prevalence of nodular thyroid disease in those workers with the highest radiation exposure when compared with less-exposed workers.[88] Most,[89,90] but not all,[81] of the initial studies on thyroid-cancer rates in contaminated areas of the Ukraine and Russian Federation did not detect excessive cancer rates in adults during the first 9–10 years after the incident. An observational study of 99 of the most severely exposed Chernobyl workers (whole-body exposure, 0.3–8.7 Gy) followed for 12–14 years did not detect any clinically overt thyroid cancer.[91] Twenty-four of these workers reported ingestion of up to 200 μg of iodine daily before and after the accident. To date, studies of cancer rates in the contaminated areas around Chernobyl have not detected increased rates of leukemia in children or adults.[82,92] In a study of 99,024 Russian liquidators living in Russian territory near Chernobyl, the incidence of thyroid cancer increased from 1992–1998 (i.e., after the latent period) compared with the male Russian population with an SIR of 4.33 (95% CI: 3.29–5.6).[93] However, the increased rate was not correlated to the external radiation dose (ERR/Gy = −2.23, 95% CI: −4.67 to 0.22).

Studies of children in Ukraine and Belarus suggest an excess risk of benign thyroid tumors in children after exposure to radiation from the Chernobyl accident.[94,95] A study of 11,613 children aged ≤18 years residing in Belarus at the time of the accident suggested an excess risk of thyroid follicular adenoma following external radiation from Chernobyl.[94] The excess odds ratio/Gy was 2.22 (95% CI: 0.41–13.1) with a linear dose response. The odds ratio decreased significantly with increasing age at exposure ($P < 0.01$) with the highest estimated radiation risk for children ≤2 years. The mean follow-up period was ~3 years with 53% of the original cohort studied in follow-up.

Fukushima Daiichi Nuclear Power Plant Complex, Japan On March 11, 2011, the magnitude 9.0 Tohoku-Pacific Ocean Earthquake occurred 130 miles off the eastern Japanese coast, resulting in a tsunami that

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

caused widespread damage at the Fukushima Daiichi Nuclear Power Plant Complex. The damage included the disabling of the cooling system and the subsequent development of fires and explosions in several nuclear reactor units. Subsequent events at the site resulted in the overheating of multiple reactors, core meltdown, and the contamination of surrounding land and coastal waters following the release of radionuclides, particularly ^{137}Cs. The radiation dose to workers and the general public during the Fukushima release was substantially smaller than the massive radiation release at Chernobyl. To date, there have been no confirmed radiation-induced deaths among workers exposed during these events.[96] Only ~30 workers received >100 mSv; these radiation levels were substantially below the radioactivity necessary to produce the acute radiation syndrome. However, this radiation level is sufficient to increase the lifetime incidence of cancer by ~1%. Radiation exposure of local residents was minimal as a result of prevailing winds blowing toward the ocean and establishment of protective measures including evacuation of persons within 20 km of the Fukushima plant, monitoring of food/water, and distribution of stable iodine pills or syrup. Monitoring of these releases in the United States indicated radioactivity levels were below a level of public health concern (i.e., <1% of the EPA Protective Action Guides).

Consumer Products

Blood

Graft-vs.-host disease is a rare, almost invariably fatal complication of blood transfusion in immunocompetent patients. Irradiating blood products with a γ-radiation dose of 15–50 Gy (1,500–5,000 rads) is currently the standard of care for the inhibition of lymphocyte proliferation and the prevention of graft-vs.-host disease.[97,98] Although some decrease in the expected survival times of less mature red cells may occur, mature red cells are highly resistant to these radiation levels. Additionally, most platelet functions, including formation of platelet proteins, are not altered by these levels.[99] The effect of radiation doses of ~50 Gy on neutrophils is more controversial; however, chemotaxis, superoxide production, and bacterial killing capacity remain intact.[100,101] Irradiation of blood products increases the potassium concentration and reduces the sodium concentration.[102] The mean potassium concentration in 20 units of plasma-reduced blood (Hct = 0.55–0.77) was 49 mEq/L (range, 39–65 mEq/L) 4 days after irradiation with 15 Gy, whereas the mean plasma potassium concentration in nonirradiated blood was 55 mEq/L at the expiration date 35 days after blood collection.[103] Plasma sodium concentrations fell concomitantly.

Food

In general, effective vaccines for the prevention of foodborne diseases in humans or animal hosts are unavailable. Irradiation of food is a safe method to substantially reduce foodborne illnesses and extend the shelf life of produce by delaying ripening.[104] Food irradiation technology uses three techniques: high-energy γ-radiation from radioactive ^{60}Co or ^{137}Cs, high-energy electrons (β-rays) emitted from an electron gun, and high-energy X-rays produced by an electron beam hitting a thin metal foil target.[105] The latter penetrates foods to a much greater depth than the few cm of an electron beam. The radiation dose required to kill simple organisms with small amounts of DNA is much higher than that required for more complicated organisms. Ionizing radiation doses of 1,000 Gy inhibit the sprouting of potatoes, reduce insects in cereal, delay the ripening of some fruits, and eradicate *Trichinella* in pork, whereas radiation doses of 50,000 Gy are necessary to eliminate viruses and bacteria in food. Intermediate doses in the range of 3–10,000 Gy reduce bacterial loads and eliminate nonspore-producing pathogens (*Salmonella*, *Yersinia*, *Campylobacter*).[106] The actual radiation dose required to sterilize food varies with the specific pathogen and the characteristics of the food.

Concerns regarding the ingestion of irradiated food include the possibility of increased chromosomal damage and the potential for vitamin loss; however, most nutritional studies, feeding trials, and toxicity studies indicate no significant health risk associated with the consumption of irradiated food.[107] These studies indicate the nutritional changes are less than those caused by pasteurization or canning. Although irradiation temporarily increases free radical formation in food, overall chemical changes in irradiated food are relatively small. Irradiating food with doses of γ-or X-rays up to 10,000 Gy at energies levels of <5 MeV does not affect the safety of food.[108,109] At energy levels of <10 MeV, this process does not produce radioactive particles (e.g., ^{24}Na) in food.[110]

DOSE EFFECT

Typically, low-LET radiation doses are categorized into low (0–0.1 Gy), medium (0.1–1 Gy), and high (>1 Gy) doses. At radiation doses of >1 Gy, acute radiation syndrome occurs; however, quantifying the health

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

effects of lower radiation doses (i.e., <0.1–1 Gy) is a complicated task similar to understanding the effects of chemical carcinogens at doses below the range of current experimental and epidemiological data. The two broad categories of health effects occurring after radiation exposure are: 1) stochastic (e.g., genetic damage, cancer) and 2) deterministic (e.g., cataracts, acute radiation sickness, vascular fibrosis). The latter broad category is also known as tissue reactions. The extrapolation of high- to low-dose data several orders of magnitude below verified data produces uncertainty in dose-response relationships near zero dose.[111]

Figure 39.3 schematically represents the extrapolation of radiation-induced stochastic effects (e.g., cancer, genetic abnormalities) from known data points to doses below the radiation doses known to cause effects. Stochastic effects assume no threshold with effects (e.g., cancer) occurring at low radiation doses near zero. Although linear and curvilinear models in the low-dose range fit the high-dose data, the difference occurs in the estimation of low-dose radiation effects. For deterministic effects (tissue reactions), curves shift to the right to account for a threshold effect. Table 39.7 outlines the NCRP estimation of acute gastrointestinal symptoms, acute deaths, and excess cancer mortality associated with specific levels of whole-body radiation.[112]

For philosophical and regulatory purposes, deterministic effects assume a threshold exists where low radiation doses do not cause effects. The data from humans exposed to high doses includes the survivors from Nagasaki and Hiroshima, patients exposed to radiation for medical purposes, and workers in earlier times who received radiation doses exceeding current standards. Examples of radiation-induced cancers include **lung cancer** in uranium miners, **bone cancer** in dial painters and patients with tuberculosis or ankylosing spondylitis

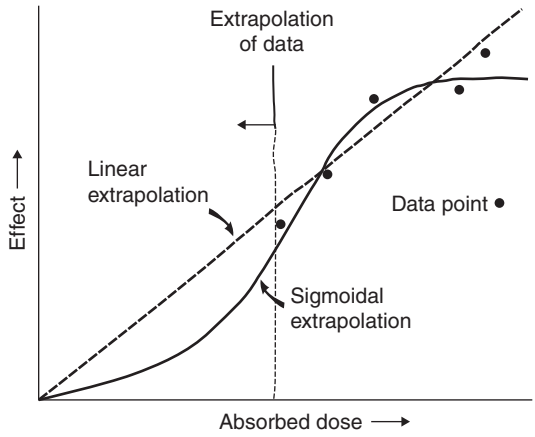

FIGURE 39.3. Schematic representation of the uncertainty of radiation-induced stochastic effects below known data points (<0.25 Gy). Extrapolation of the data below known data points to zero dose may be linear or sigmoidal. (Loken).[113]

ingesting radium, **thyroid cancer** in children receiving radiation for enlarged thymus or *Tinea capitis*, **breast cancer** in patients treated with fluoroscopy for tuberculosis and women receiving radiation treatment for postpartum mastitis, **leukemia** in patients treated with radiation for ankylosing spondylitis, and **solid tumors** and **leukemia** in the survivors at Nagasaki and Hiroshima. In the atomic bomb survivor cohort, significant dose-responses were observed for mortality from several solid tumor sites including esophagus, stomach, colon, lung, breast, ovary, urinary bladder, multiple myeloma, and central nervous system tumors (e.g., brain).[114]

Factors

The radiation dose as measured by the absorbed dose (mSv) received by a patient depends on several factors

TABLE 39.7. Estimated dose-response of acute symptoms, acute death with/without medical care, and excess risk of fatal cancer in healthy, noninjured adult emergency workers exposed to whole-body radiation based on National Council on Radiation Protection and Measurements data. Acute deaths typically occur 30–180 days after exposure. Gastrointestinal (GI) symptoms include nausea and vomiting beginning within 4 hours of exposure. The lifetime excess risk of death from cancer is the cancer mortality above the 24% of the general population likely to die from cancer. (Adapted from NCRP).[112]

Acute Whole-Body Dose (Sv)	Acute GI Symptoms (%)	Deaths *Without* Medical Care (%)	Deaths *With* Medical Care (%)	Lifetime Excess Risk of Fatal Cancer (%)
0.1	0	0	0	1
0.5	0	0	0	4
1	5–30	>5	0	8
1.5	40	<5	<5	2
2	60	5	<5	16
3	75	30–50	15–30	24
6	100	95–100	50	>40
10	100	100	>90	–

TABLE 39.8. Shielding required to reduce the energy of specific photons by 50% (half-layer value) for water, concrete, and lead in centimeters. (Mettler).[17]

Photon (MeV)	Water (cm)	Concrete (cm)	Lead (cm)
0.1	4.2	1.7	0.015
0.2	5.0	2.3	0.065
0.4	6.5	3.0	0.27
0.6	7.8	3.6	0.5
0.8	8.8	4.0	0.7
1.0	9.6	5.0	0.9
2.0	14.0	7.0	1.3
5.0	23.0	11.0	1.5

including: 1) distance between the source and the patient, 2) time in the field of radiation, 3) extent of shielding between the patient and the source, and 4) the radiation amount and quality. Distance probably is the most effective way to reduce the radiation dose because the absorbed dose varies as the inverse square of the distance between the patient and the radiation source. Hence, doubling the distance decreases the radiation dose to $^1/_4$ of the previous value (1\distance^2). The amount of time spent in the radiation field is directly proportional to the absorbed dose. Doubling the amount of time in the field also doubles the absorbed dose. The reduction of the absorbed dose resulting from the interposition of shielding between the patient and the source of radiation depends on the density of the shield.

Lead is the usual metal used to shield patients, as a result of its high density. The half-value layer (HVL) and the tenth-value layer (TVL) measure the effectiveness of the shielding; these values represent a reduction of the absorbed dose by 50% and 90%, respectively.

Table 39.8 lists the amounts of different shielding types necessary for a 50% reduction in the radiation delivered by photons. As seen in Table 39.8, the effectiveness of shielding also depends on the energy of radiation source. Unfortunately, shielding during most radiation accidents is not very effective because the very high energy of the radiation emitted during these accidents easily penetrates the shielding.[115]

Stochastic Effects

Stochastic effects result from modification of an irradiated cell rather than cell damage. Tumors, teratogenic abnormalities (primarily mental retardation), and genetic effects are the classic examples of stochastic effects. The occurrence of these delayed effects is probabilistic; the expression of these effects depends on the number of cells initially modified and the size of the cell population. Increasing the dose increases the chance a cancer will appear; however, larger doses do not enhance the disease's severity. Consequently, only a small fraction of people exposed to a specific radiation dose will develop stochastic effects because cellular repair and defense mechanisms reduce the number of modified cells. Although a DNA repair mechanism may operate well, especially in the absence of cell division, safety concerns dictate the acceptance of the absence of threshold for effects related to low radiation doses. Therefore, stochastic effects potentially can occur at substantial distances from the radiation source.

Deterministic Effects (Tissue Reactions)

Deterministic (nonstochastic) effects result from radiation-induced cellular destruction, acceleration of normal physiological process of programmed cell death (apoptosis), and the resulting organ dysfunction. The severity of the health effect depends on several factors including total radiation dose, delivered dose rate (e.g., fractionated doses are typically 4-fold less potent than the same single radiation dose), radiation type, and tissue volume radiated.[116] Deterministic effects manifest within hours to days in response to radiation doses of >0.25–1 Sv as a direct result of the termination of cell division and excessive cell death; late deterministic effects (e.g., cataracts) may occur years after radiation exposure. The appearance of effects from the destruction of irradiated cells depends on cell loss sufficient to impair function; hence, there is a threshold below which these acute effects do not manifest. Deterministic effects are predictable in an individual depending on the radiation dose, whereas stochastic effects (e.g., cancer) develop in a few individuals exposed to the same radiation level. Teratogenic effects from *in utero* exposure may display deterministic or stochastic characteristics. Some deterministic effects (e.g., fibroatrophy, vascular fibrosis, cataracts, infertility, growth retardation, hypothyroidism) are delayed; however, the expression of these changes is not related to age as occurs with cancer. The amount of radiation-induced damage depends on the sensitivity of the organ as well as the absorbed dose.

The incidence and latency period for early prodromal symptoms of the acute radiation syndrome are dose-related. Vomiting occurs in 50% of patients within 3 hours of exposure to 2 Gy, whereas reduction of the lymphocyte count begins within 48 hours of acute exposure to 1–2 Gy. The LD_{50} for uniform low-LET radiation is ~3 Gy for cancer patients compared with ~4.5 Gy for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 39.9. Approximate dose-effect relationship of whole body ionized radiation. (Adapted from Mettler and Voelz).[118]

Dose[a] (Gy)	Prodrome[b]	Clinical Features	Prognosis[c]
0.05–0.1	Absent	None	Survival
0.15–0.2	Absent	Chromosomal aberrations in cultured blood lymphocytes; reduction of sperm count with nadir at 45 days after exposure. No symptoms	Survival
0.5	Absent	Minor reduction in leukocytes and platelets	Survival
1	Mild, <48 hours	Detectable bone marrow depression (Hematopoietic syndrome begins), nausea/vomiting in ~10%	Survival highly likely (>90%)
2	Mild–Moderate, <24 hours	Nausea/vomiting in ~50% with marked reduction in leukocytes and platelets	Survival likely
2–3.5	Moderate		Probable survival
3.5–5.5	Severe, <8–12 hours	Moderate–severe bone marrow damage; slight GI damage (Nausea/vomiting ~90%, diarrhea ~10%)	50% mortality within 6 weeks
5.5–7.5	Severe	Pancytopenia; moderate gastrointestinal damage	100% morality from bone marrow failure within 30 days absent treatment
7.5–10	Severe	Marked gastrointestinal and bone marrow damage, hypotension	Rare survival at lower end of exposure with best medical care; death typically within 1–2.5 weeks
10–20	Immediate	Nausea/vomiting in all patients; severe gastrointestinal damage, pneumonitis, altered mental status	Death is certain within 1–2 weeks
20–30	Immediate	Cardiovascular/CNS syndrome (nausea/vomiting, hypotension, shock, convulsions, fever)	Death is certain within 1–5 days

[a] Whole-body absorbed dose in Gray (Gy); [b] Onset of symptoms is dose and dose-rate dependent; NA – not applicable; [c] Without therapy.

previously healthy patients receiving supportive care.[117] Survival is unlikely when the radiation dose exceeds 8 Gy. Low-LET radiation doses of 10–50 Gy usually cause a fatal gastrointestinal syndrome within several weeks, whereas doses of >50 Gy produce a fatal neurological syndrome within several days. Neutrons have a higher linear energy transfer (LET) compared with X- and γ-rays by a factor of 2–3.

The constellation of clinical signs and symptoms of the acute radiation syndrome follows a predictable pattern based on the inherent sensitivity of these cells. After absorbed doses of <1 Gy, tissue damage is not usually severe; most cells initially survive; however, malignant transformation may occur much later.[118] Generally, the larger the dose, the more severe and the sooner symptoms appear. Table 39.9 outlines the features of the acute radiation sickness based on whole-body radiation dose.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The biological effects of ionizing radiation depend on several factors including total dose, dose rate, volume and type of tissue irradiated, specific anatomical part irradiated, and individual susceptibility (i.e., associated trauma and disease, metabolic polymorphisms, altered DNA repair capacity, hormonal imbalance, suppressed immunity). Maximum sensitivity of cells to ionizing radiation occurs during the mitotic phase of the cell cycle; therefore, rapidly dividing tissues (e.g., lymphocytes, myeloblasts, endothelial cells) are very sensitive to the effects of ionizing radiation. Similarly, embryos are much more sensitive than adults.

Biological Response

During passage through tissue, ionizing radiation transfers virtually all its energy to electrons that subsequently lose their energy by ionizing the irradiated medium. Directly ionizing particles (α, β) are charged; they deposit their energy by electrical interactions with nearby orbital electrons. Low-LET, indirectly ionizing radiation (i.e., γ-rays, X-rays) liberates orbital electrons that interact with other atoms to produce ions. The deposition of energy by neutrons is more complex. For neutrons with energies below 20 MeV, 90% of the absorbed energy in tissue results from protons that recoil

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from elastic collisions with neutrons.[9] As the energy of the neutron exceeds 20 MeV, inelastic scattering (i.e., emission of photons after the collision) and the spallation process (i.e., fragmentation of the nucleus with emission of particles and nuclear fragments) become more dominant processes.

Although the physical interaction that causes the formation of ions occurs in femtoseconds (10^{-13}–10^{-14} seconds), chemical events produce tissue damage following the initial ionization of atoms and molecules within the tissues. The most important initial radiochemical reactions occur in water because the average cell contains 70% water. Several important reactive species form from the radiolysis of water by ionizing radiation including: 1) aqueous electrons (e_{aq}), 2) hydroxyl free radicals, and 3) hydrogen free radicals. Initially, ionizing radiation produces aqueous electrons that subsequently form free radicals. The free radicals are uncharged (neutral), highly reactive atoms, or molecules with unpaired electrons. These highly oxidizing compounds readily react with cellular components (e.g., DNA) to destroy chemical bonds and disrupt cellular processes. This indirect reaction of free radicals with DNA is probably a more important cause of biological damage than the direct interaction of electrons with DNA, cellular membranes, or protein synthesis.

Biological damage from ionizing radiation results from direct and indirect effects. The former involves cellular DNA damage (double-stranded, single-stranded, base damage); the most critical cause of radiation-induced cell death is DNA double-strand breaks. Indirect effects involve the interaction of ionizing radiation with free or bound intracellular water to form reactive oxygen species (free radicals). Approximately $^2/_3$ of biological damage from high-energy photons released by X- and γ-rays results from the generation of free radicals and proinflammatory chemokines/cytokines (e.g., transforming growth factor-β, tumor necrosis factor, IL-1, IL-6), whereas direct DNA damage accounts for the remaining damage.[119] The covalent bonds in DNA molecules in the chromosomes are the primary molecular target with repair or miss repair of critical DNA lesions determining sensitivity of somatic and germline cells to ionizing radiation. The major types of damage to the chromosomes include alterations of DNA bases, single- and double-stranded chromosome breaks, formation of DNA adducts, chromosomal aberrations, aneuploidy (i.e., abnormal number of chromosomes), and altered DNA methylation. Double-stranded breaks in the chromosomes are not repaired easily; therefore, this type of damage and the subsequent loss of the associated gene products coded by the affected segment of DNA are important mechanisms of radiation-induced cell damage.[120] These molecular changes produce functional changes in the signaling pathways critical to cellular function including dysregulation of DNA repair mechanisms, alterations in cyclin-dependent kinases and cell cycle progression, posttranslational modifications of proteins, suppression of apoptotic rates, changes in secretory factors that stimulate DNA replication and transcription, and alteration of gap-junction mediated intercellular communications.

Radiation-induced, chemical-induced, and spontaneous cancers share a similar complex, multistep process. Animal experiments suggest low-dose radiation (i.e., ≤0.1 Gy) affects primarily initiation, whereas high-dose radiation (≥1 Gy) also enhances later stages (promotion, progression).

Tissue Sensitivity

Radiosensitivity of specific tissues depends on mitotic activity and regenerative processes. For low-LET radiation, the most sensitive stages to cell death are mitosis and late G_1. The survival of cells decreases with increasing radiation doses. All cells die at radiation doses of several hundred Gy; at radiation doses of 1–2 Gy, most cells will not divide.[121] Tissue susceptibility to ionizing radiation depends directly on the cellular proliferation rate and inversely on the degree of cell differentiation, as defined by the law of Bergonie and Tribondeau in 1906.[122] Cell survival is relatively lower with high- than low-LET radiation. In contrast to low-LET radiation, cell survival is relatively independent of the dose rate for high-LET radiation. Radiation-induced cancers are pathologically indistinguishable from cancers in the same tissues caused by other carcinogens. Although radiation causes a wide variety of tumors as determined from epidemiological studies on the survivors of the atomic bombs dropped on Hiroshima and Nagasaki, susceptibility of individual tissues to radiation-induced cancer varies widely.[123] Table 39.10 lists the relative sensitivities of different tissues to radiation-induced cancer.

Latency

The acute expression of tissue damage depends primarily on the kinetics of cell loss rather than functional deficiencies in irradiated, viable cells for deterministic effects. Tissues with rapid cell turnover (e.g., epithelium of the gastrointestinal tract, blood cells) react earlier than tissue with long-lived cells (e.g., thyroid, central nervous system). For low doses, the latency period prior to the appearance of gross tissue injury is dependent on the dose, whereas the latency

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 39.10. Relative susceptibility of various tissues to radiation-induced cancer based on increased incidence/unit dose. (Adapted from Mettler and Upton).[123]

Relative Susceptibility	Tissues
High	Bone marrow (leukemia except CLL), female breast, salivary glands, thyroid (females > males)
Moderate	Bladder, colon, liver, lung, ovary, skin, stomach
Low	Bone, brain, connective tissues, kidney, larynx, nasal sinuses
Very Low/Absent	Cervix, CLL, esophagus, gallbladder, Hodgkin's disease, lymphatic system and myeloma, melanoma, muscle, pancreas, prostate, testes, uterus

Abbreviation: CLL = chronic lymphocytic leukemia.

period is dose-independent for high radiation doses.[124] Table 39.11 summarizes the effects and doses associated with acute radiation injuries to some human organs.

Pathological Changes

Lethal radiation doses produce widespread destruction of tissues in radiosensitive organs (i.e., high metabolic rate, rapidly proliferating cells including the lining of the small bowel, bone marrow, salivary gland) and superficial dermal tissue exposed to the highest radiation dose. Organs with less radiosensitivity (i.e., slowly proliferating cells) include blood vessels, connective tissues, liver, and kidney. The pathological effects of radiation result primarily from disruption of cell reproduction along with some cell death. Cells sensitive to radiation include: 1) rapidly dividing cells, 2) undifferentiated cells, and 3) cells dividing at the time of radiation exposure.[125] Cells relatively resistant to radiation include liver, kidney, muscle, cartilage, nervous tissue, and the nonmarrow portion of the bone. Radiosensitive cells (e.g., immature spermatogonia, oocytes, lymphocytes) undergo degenerative changes within minutes of exposure to radiation doses of ~1 Sv; however, most pathological evidence of destruction becomes apparent only after the dying cells fail to divide and regenerate.

Cell necrosis usually occurs during or shortly after mitosis, particularly in rapidly dividing cells that populate the skin, gastrointestinal tract, and hemopoietic organ systems.[126] The extent of damage revealed by autopsy depends on the period of survival following exposure to the lethal radiation dose and the ability of surviving stem cells to replace lost cells. Radiation-induced injury ranges from immediate inhibition of mitosis in the epidermis and germinal epithelium of the gastrointestinal tract to degenerative changes in the lens and vessels months to years later. Exposure to high radiation doses causes a gradual reduction in the patency of the capillaries and the number of capillary beds. These changes are nonspecific including hypocellular bone marrow, loss of follicles in the spleen, prominence of nuclear fragments, and atrophy of the villi and glands in the gastrointestinal tract.[127]

Thyroid

Early radiation-induced alterations of the thyroid include vacuolization and eosinophilic granulation in the follicular cell cytoplasm, nuclear pyknosis, phagocytosis, and stromal edema with high radiation doses producing severe degenerative changes including desquamation of the follicular epithelium, extrafollicular colloid, and Hürthle cells.[128] Chronic pathological changes include interstitial fibrosis, vascular damage (intimal thickening and hyalinization of arterioles and medium-sized arteries), and focal calcification in the internal elastic membranes.[129,130] Benign thyroid nodules commonly occur after radiation, particularly multinodular goiter; thyroid cancers primarily involve papillary thyroid carcinomas.[130]

Bone Marrow

The most dramatic changes occur in the blood following exposure to ionizing radiation, with lymphocyte depletion appearing within several hours of exposure. There is a dynamic balance between the depletion of hemopoietic elements and the regeneration of these elements depending on the life span of the marrow stem cells and the time since exposure. The marrow can regenerate at acute radiation doses up to 6 Gy.[131]

Central Nervous System

The lack of rapid cell turnover limits the pathological evidence of acute injury to the brain including aggregations of granulocytes along the blood vessels, cerebral edema, and some localized changes (e.g., damage to the granular cell layer of the cerebellum).[125] Pathological changes include disruption of the blood–brain barrier, meningeal inflammation, impaired capillary circulation, interstitial edema, petechial hemorrhages, and hypertrophy of perivascular astrocytes.[132] Neurological symptoms in a patient dying 49 hours after receiving an 8.8-Gy whole-body dose of neutron radiation resulted from vascular damage and impairment of the cerebral circulation rather than primary destruction of

TABLE 39.11. Latency, threshold, cause, and target cells of acute radiation injury (deterministic effects) on some human tissues from single radiation doses and single-dose equivalents calculated from fractionated radiation doses. Before the expression of gross tissue damage from inhibition cell replication reflected in the threshold dose column, the latency period from this damage is dose-dependent at low radiation doses and dose-independent at high doses. Changes in organ function occur at radiation doses well below the listed threshold of clinically apparent tissue damage (e.g., the sperm count begins to decrease ~1½ months after a radiation dose of 1 Gy, reduction of absolute lymphocyte count within several hours after radiation exposure with a nadir in ~48 hours and duration up to several weeks). Oligospermia may begin after a radiation dose of 0.15 Gy and azoospermia 10 weeks after a radiation dose of 1 Gy. (Adapted from Hendry).[124]

Tissue (Effect)	Latency Period	Threshold Dose (Gy)	High Incidence Dose (Gy)	Cause	Target Cells
Eye (cataract)	>1 year	2[a]	10	Abnormal cell maturation	Fiber-forming lens, epithelial cells
Whole body growth, Retardation	Age[b]	≤7.5	—	↓Growth hormone[c]	Hypothalamic pituitary axis
Lung (pneumonitis)	$M = 3$ months (1–7 for 90% of patients)	8.2	>10	Reduced barrier and alveolar surfactant	Type II alveolar cells[d]
Ovary					
(Infertility)	<1 month	≤4 (↑ younger women)	~10	Ovarian failure	Oocytes
(Sex development)	Age[b]	~10	—	↓Estrogen	Ovary
				↓Gonadotrophin	Pituitary
Testes					
(Sexual development)	Age[b]	~10	—	↓Testosterone	Leydig cells Pituitary
				↓Gonadotrophin	
Thyroid					
(↓ Growth, Metabolism)	<1 year	≤7.5	—	Hypothyroidism	Follicular cells

Abbreviation: M = mean (90% range, 1–7 months).

[a] In 2007, the ICRP estimated the occurrence of lens opacities may occur after single, acute radiation exposures of 0.5–2 Gy or following protracted radiation exposures of 5–6 Gy based on their review of animal and epidemiology studies. The exact threshold is unclear because of the heterogeneity of the data, multiple lens opacity classification systems, and short follow-up periods; [b] Age-dependent; [c] High doses, cartilage and bone are affected at lower doses by effects on chondrocytes; [d] Possibly endothelial cell involvement.

neurons.[133] Only minimal amounts of neuronal damage and glial reactions occurred in this case; death resulted from cardiac failure, increased intracranial pressure, and cerebral anoxia. Within 4–5 months of exposure to an absorbed radiation dose of >15 Gy, focal necrosis, calcifications, gliosis, and demyelinization of the white matter can appear. Little direct damage to neurons occurs at doses of <60 Gy.[131]

Heart

Radiation reduces the number of capillary beds following exposure to doses of >15 Gy. Although little damage occurs in the nonproliferating cells of the myocardium, the subsequent reduction in blood flow can cause secondary myocardial necrosis, pericardial effusions, and myocardial fibrosis.

Intestines

The rapidly dividing epithelial cells in the mucous membranes of the mouth and oropharynx are radiosensitive, resulting in the development of painful oropharyngeal lesions that persist for weeks. Altered gastric emptying and reduced gastrointestinal motility produce vomiting, diarrhea, and abdominal cramps. Loss of the mucosal barrier and changes in the normal gastrointestinal flora allow systemic access and predispose the patient to sepsis. Poor gastrointestinal function results in rapid weight loss. Radiation-induced injuries range from loss of crypt cells at absorbed doses of 1 Gy to complete loss of villi and denudation of the entire epithelia during severe forms of the gastrointestinal syndrome. Damage to the capillary endothelium results in fibrosis of the muscular layer and the serosa. A 35-year-old man died from the gastrointestinal syndrome and multiorgan failure 82 days after receiving 16–25 Gy of γ-ray and neutron radiation, despite receiving peripheral blood stem cell transplantation on days 6 and 7.[134] Pathological findings included blood clots throughout the gastrointestinal tract, ablated mucosal epithelial cells, mucosal congestion and bleeding, dyskaryotic cells in the stroma, submucosal fibrosis, and smooth muscle degeneration.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. A few squamous cells appeared in the esophagus along with a few epithelial cells in the descending colon, sigmoid colon, and rectum; however, no remnants of epithelial cells remained in tissues from the stomach to the ascending colon, probably reflecting the position of the abdomen at the time of irradiation and resulting in differences in the radiation dose delivered to various parts of the gastrointestinal tract.

Liver

Damage to the sinusoidal endothelium in the lobules can produce obstruction of the central lobules, secondary loss of hepatocytes, and portal hypertension within 6 weeks of exposure.

Lung

Ninety days after exposure to doses of 10 Gy, acute pneumonitis appears as a result of the occlusion of capillaries and loss of endothelial cells. Depletion of type II pneumocytes and surfactants precedes the development of pneumonitis. Hypoxia and interstitial edema of the lungs may develop during severe radiation syndrome.[135]

Kidney

Reduction of the cells lining the tubules occurs acutely after acute radiation doses of 10 Gy. Occlusion of the capillaries leads to loss of nephrons 4–18 months following exposure. Eventually, damage to the glomeruli and secondary hypertension appear.

Skin

In contrast to the acute radiation syndrome, the severity of skin damage depends on the local radiation dose and depth of dermal penetration rather than the whole-body radiation dose. Alpha particles do not penetrate the horny layer of the skin (i.e., <0.1 mm); however, prolonged contact produces serious burns from the highly ionizing properties of α-particles (30,000 ion pairs/cm air). Beta particles can penetrate skin (i.e., 1–2 cm) causing more intense, localized dermal damage than α-particles. Although γ- and X-rays are weakly ionizing, they penetrate deeply (i.e., many cm) into the body, depending on the tissue density with dermal damage inversely proportional to the energy of the γ- or X-ray. Neutrons penetrate >2 cm into the skin where collisions with stable atoms produce protons, α- and/or β-particles, and γ-rays. The relative biological effectiveness of neutrons is greater than that of other forms of electromagnetic radiation.

Transient vasodilation, interruption of cell proliferation in the basal layer, and thinning of the prickle cell layer result after exposure to acute radiation doses of 3–9 Gy. Initial erythema probably results from the release of vasoactive amines, whereas the second erythematous phase develops 2–3 weeks after the radiation exposure, depending on the radiation dose and skin tolerance. Animal models suggest the repair of radiation-induced intracellular injury is complete within 6 weeks in the absence of permanent damage; subsequent dermal changes result from capillary damage, fibrosis, and local ischemia. This biphasic late phase of skin damage results from narrowing of the blood vessels from fibrosis and obliteration of the capillaries secondary to endothelial damage.[136] The resulting vascular damage leads to ischemic necrosis. The latter phase is associated with mauve or blue discoloration of the skin. Secondary ulceration occurs from infection or dehydration of the dermis in patients with severe moist desquamation. Ulceration of the skin, loss of hair follicles, and damage to sweat glands occur when radiation exposure exceeds 20 Gy.

CLINICAL RESPONSE

The clinical pattern of acute radiation syndrome (ARS) varies in intensity, duration, and onset, depending on the extent of dose-dependent damage to tissue.[137] Variations in radiation exposures include whole-body exposure (acute radiation sickness), localized exposure from handling highly radioactive sources, internal contamination from pulmonary, gastrointestinal, or dermal absorption of radioactive nucleotides, and external contamination of clothing and exposed skin. ARS results from acute exposure to whole-body radiation doses of >1 Sv characterized by dose-dependent dysfunction of the hematopoietic system, gastrointestinal tract, and central nervous system.[138] The biological effectiveness of γ- and β-radiation is the same; therefore, the gray (Gy) and the sievert (Sv) are equivalent measures of the biological effect of an absorbed radiation dose from these two types of radiation. ARS is a rare event that occurs following the accidental release of high γ-rays, X-rays, or neutron radiation doses at large nuclear facilities (e.g., power plants, research/medical facilities, commercial organizations), the detonation of nuclear bombs, or the improper disposal of nuclear material. The importance of the initial symptoms of ARS results from the positive association between onset of prodromal symptoms and the amount of radiation received by the victim. Because of the prognostic value of the early onset of prodromal symptoms, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

initial clinical pattern is an important early prognostic indicator to help triage victims based on their ultimate outcome.

Deterministic Effects

Deterministic clinical effects (tissue reactions) occur when the radiation dose is sufficient to damage enough critical cells in an organ to cause dysfunction (e.g., neutropenia, bone marrow failure). The severity of injury is dose-dependent (i.e., dose determines the effect) with a threshold and delivered at relatively high dose rates (e.g., >~0.05 Gy/hour).[119] Generally, the threshold for acute radiation sickness is ~1 Gy. In contrast to deterministic effects, stochastic effects occur in a random, probabilistic association with no threshold (e.g., cancer, birth defects). The risk of a stochastic effect increases with dose, but not the severity of the effect. Although genetic hereditary effects occur in animals exposed to radiation, human studies have not observed these effects.[139]

Acute Radiation Sickness

Sufficiently high radiation exposure over a short time causes acute radiation sickness (acute radiation syndrome, multiple organ dysfunction syndrome, radiation sickness, radiation poisoning, ARS). Although the biological effect of radiation is dose-dependent, most radiation exposures do not irradiate the body uniformly; additionally, sensitivity of the tissues to radiation varies (e.g., abdominal radiation produces more acute effects than an equivalent radiation dose to the chest or an extremity).[137] Factors affecting the response to a radiation dose include total radiation dose, dose rate, radiation quality, fraction of the body irradiated, amount of shielding, and a variety of individual factors determining radiation sensitivity (e.g., demographic, dietary, genetic, age, sex, preexisting medical conditions). Acute radiation sickness occurs following whole-body or significant partial-body irradiation exceeding 1 Gy delivered at a relative high dose rate. Acute radiation sickness comprises four life-threatening syndromes (hematopoietic, gastrointestinal, neurovascular, cutaneous); the clinical pattern of these syndromes includes: 1) a prodromal phase within the first few hours, 2) a latent period that decreases with dose, 3) the manifest phase of the illness, and 4) death or a recovery period extending weeks to months.[118,140] The clinical features of ARS may present as a combination of multiorgan effects.

Figure 39.4 demonstrates the time sequence of the major events that comprise the acute radiation syndrome based on clinical signs and absorbed radiation dose. Although the clinical course following radiation exposure depends primarily on the absorbed whole-body dose, variation in the presentation of symptoms will occur due to various factors including the underlying health of the patient, the type of medical treatment, environmental conditions, and the extent of associated trauma.[141] Cells that replicate rapidly (e.g., intestinal crypt cells, lymphohematopoietic elements, spermatocytes) are the most radiosensitive.

Ionizing radiation shortens the life span primarily from the development of cancer rather than an acceleration of the aging process.[143] Classically, mortality from diseases other than neoplasms is not consistently associated with epidemiology studies of radiation exposure;[121] however, aging and radiation exposure share similar pathological mechanisms, including oxidative stress, inflammation, stem cell exhaustion, chromosomal damage, and apoptosis.[144] Epidemiological evidence from Nagasaki and Hiroshima suggests low to moderate radiation doses affect mortality associated with some noncancerous diseases (e.g., cardiopulmonary disease, stroke, digestive disease); these studies do not detect increased mortality from Alzheimer's disease, type 2 diabetes, or infectious diseases.[145]

Prodrome

Nonspecific prodromal symptoms appear promptly within 1–2 hours to several days of radiation doses of >1 Gy. Although symptoms of stress may appear, absorbed radiation doses of <0.15–0.5 Gy are not typically associated with prodromal symptoms.[146] Prodromal symptoms include nausea, vomiting, diarrhea, anorexia, fatigue, headache, dermal erythema, erythematous mucous membranes, and glandular swelling, with higher doses producing increased severity, more rapid onset, and longer duration. Prodromal symptoms may cause significant dehydration. The onset of nausea and/or vomiting within 12–24 hours indicates a medically significant exposure beginning with the appearance of nausea. Vomiting 2–5 hours following exposure indicates a potentially severe radiation exposure; most individuals (80–100%) with total-body radiation of >3.5 Gy vomit.[141] However, estimation of the radiation dose based on the onset of emesis alone is imprecise and may produce high false-positive rates.[147] Serious radiation exposures may also occur in the absence of vomiting.

At Chernobyl, nausea and vomiting appeared in the most severely exposed victims within 15–30 minutes following the explosion; the onset of vomiting also depends on the radiation dose rate.[148] Among the 126 victims manifesting one or more prodromal symptoms within

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 39.4. Schematic representation of time sequency for major clinical features of the acute radiation syndrome based on clinical signs and absorbed radiation dose. (Adapted from Llewellyn).[142]

36 hours of the explosion, 99 patients developed acute radiation sickness. The onset of bloody diarrhea within 1 hour of exposure, the appearance of mental confusion, ataxia, convulsion, and coma within 2–6 hours of exposure, or the development of hyperthermia, fever, chills, or hypotension within 24 hours of exposure in the absence of associated trauma or illness suggest a fatal outcome.[142]

Latent Period

The period between the cessation of prodromal symptoms and the onset of acute radiation syndromes depends on the absorbed dose.[149] For whole-body radiation doses of 2.5–4 Gy, the prodromal symptoms disappear within 24–48 hours before evidence for the hematological syndrome occurs 1–3 weeks later; the whole-body radiation dose causing death within 60 days in 50% of irradiation patients not receiving medical treatment is ~3.5 Gy.[116] Sepsis and gastrointestinal abnormalities develop within 7 days of the end of the prodromal period at doses of 4–6 Gy. Survival may occur in patients receiving aggressive supportive care following exposure to whole-body doses of 5–6 Gy. Supralethal doses of >15 Gy are associated with the appearance of cardiovascular dysfunction and mental status changes within hours of the radiation exposure.

Subsyndromes

Hematopoietic The hematopoietic subsyndrome results from the loss of critical hematopoietic stem and progenitor cell populations, resulting in life-threatening diffuse bone marrow suppression. The metabolic activity of the bone marrow is high, daily producing billions of cells that are immature and highly radiosensitive. Although changes in the bone marrow are detectable at ~0.2 Gy, clinically *apparent* findings do not occur until the absorbed dose exceeds 0.75–1.0 Gy. Clinically *significant* blood disorders develop following whole-body doses of >2 Gy from bone marrow suppression and the exponentially increasing death of bone marrow stem and progenitor cells. Stem cell damage in the bone marrow and the lymphatic tissue occurs following exposure to low- to mid-lethal doses of whole-body radiation (i.e., 2.5–5 Gy) along with depression of the production of blood elements. Clinical manifestations of bone marrow hypoplasia and aplasia include bleeding, infection, and poor wound healing.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Maximal bone marrow depression occurs several weeks after exposure. The associated clinical conditions (i.e., hemorrhage, increased susceptibility to infection) develop 10 days to 6–8 weeks after radiation exposure, with pancytopenia and recovery of the marrow occurring earlier with radiation doses up to 6–7 Gy.[148] Hematopoietic recovery depends in part on the survival of foci of hematopoietic activity following nonhomogeneous radiation exposure, particularly relatively radioresistant stem or accessory cell irradiation during their noncycling (G_o) state. The nadir for the neutrophil count following radiation doses of ~1 Gy appears ~30–40 days postexposure, whereas the nadir for platelets at this dose occurs ~25–30 days after radiation exposure. Before decreasing, neutrophils and other granulocytes may transiently increase following radiation doses of <5 Gy. Figure 39.5 demonstrates the approximate time course of dose-related changes in granulocytes, lymphocytes, and platelets following whole-body radiation doses of 1–5 Gy. The occurrence of severe granulocytopenia within 7–10 days is a poor prognostic sign. The experience at Chernobyl suggests bone marrow recovery can occur following doses up to 9 Gy. Death from the hematopoietic syndrome may occur following radiation doses of 2–6 Gy 2–8 weeks after exposure when infection and/or bleeding results from neutropenia and thrombocytopenia, respectively. Mature red blood cells and platelets lack a nucleus and are radioresistant. The long lifespan of erythrocytes limits the effect of anemia during this time. Lung or kidney damage may appear months to years after radiation exposure from sclerosis of capillaries beds.

LYMPHOCYTE COUNT The earliest change in hematological indicators is the reduction of the total absolute lymphocyte count; these changes begin within several hours with a nadir in ~48 hours and duration up to several weeks.[137] Figure 39.6 displays Andrew's lymphocyte depletion curve; this curve associates the reduction in absolute lymphocyte counts during the first 2 days after acute radiation exposure with severity of the radiation-induced injury. Absolute lymphocyte counts of <1,000 cells/mm^3 4–7 days postexposure indicate serious irradiation (>1 Gy) and counts of <100 cells/mm^3 imply a probably lethal dose (>5–6 Gy).[150] Lymphocytes

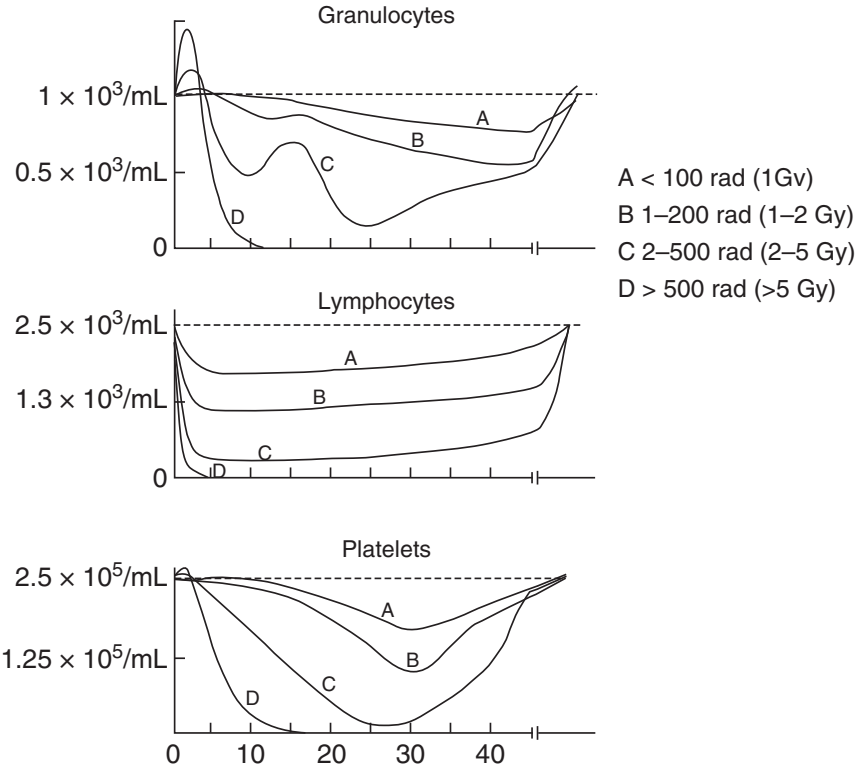

FIGURE 39.5. The time- and dose-dependent reduction of granulocytes, lymphocytes, and platelets following four progressively increasing whole-body radiation doses: A = <1 Gy, B = 1–2 Gy, C = 2–5 Gy, and D = >5 Gy. The dotted line represents the baseline value of these blood elements. The vertical axis represents the absolute count, whereas the horizontal axis represents time in days. (Adapted from Mettler and Upton).[123]

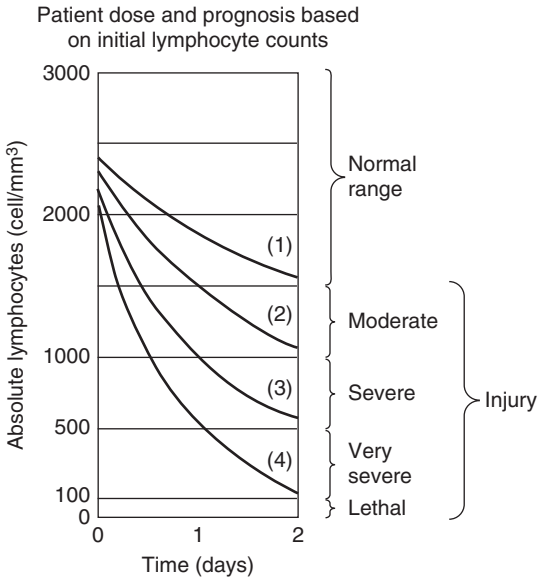

FIGURE 39.6. Andrew's lymphocyte depletion curve estimates the severity of the acute radiation syndrome based on the reduction in the absolute lymphocyte count within the first 2 days after exposure. The vertical axis represents the absolute lymphocyte count; the horizontal axis represents time after radiation exposure in days. The numbers on the curves represent the following whole-body radiation doses: 1) = 3.1 Gy, 2) = 4.4 Gy, 3) = 5.6 Gy, and 4) = 7.1 Gy. (Adapted from Goans).[152]

may decrease in trauma patients (e.g., burns) from the injury alone.[151]

FEVER AND INFECTION The presence of a temperature of >37°C within 5 hours after radiation exposure suggests a radiation dose of ≥2.5 Gy, whereas fever after the prodromal period typically occurs because of infection, dehydration, or other etiologies.[153] An agranulocytic fever appeared in 12% of patients exposed to 1–2 Gy at Chernobyl, whereas the incidence of fever was 70–80% at a dose of 4–5 Gy; the incidence of fever increases to ~100% at whole-body doses of >5–6 Gy.[148] Following radiation doses of <5 Gy, the source of most fevers in the patients was not identified; no deaths resulted in patients treated with broad-spectrum antibiotics. No infections developed in these patients past the period of agranulocytosis. Above the 5–6 Gy dose range, herpes simplex and cytomegalovirus infections exacerbated terminal bacterial infections; these viruses were the main causes of death in the patients dying after the period of agranulocytosis. These infections were resistant to the available antimicrobial agents; however, the effectiveness of antiviral agents has significantly improved since the Chernobyl accident in 1986.

GASTROINTESTINAL SUBSYNDROME Acute whole-body radiation exposures of >6 Gy produce clinical features of gastrointestinal syndrome secondary to necrosis of intestinal mucosal stem cells and disruption of the mucosal barrier. Massive apoptosis of the gastrointestinal epithelium followed by destruction of the mucosal epithelial barrier causes fluid/electrolyte loss, sepsis, and intestinal bleeding. When the dose of radiation exceeds 7 Gy, gastrointestinal symptoms and signs begin before the appearance of hematological abnormalities (e.g., pancytopenia). At radiation doses of >12 Gy, the mortality rate is greater for the gastrointestinal than the hematopoietic syndrome.[154] The initial prodromal symptoms of the gastrointestinal syndrome are similar to those of the hematopoietic syndrome; however, 5–26 days postexposure, severe diarrhea develops that progresses to bloody diarrhea and fluid/electrolyte loss as a result of damage to the gastrointestinal epithelium.[134] Abdominal distention, dehydration, hypovolemic shock, sepsis secondary to enteric bacteria, multiorgan failure, and death complicate the clinical picture. All patients developing the gastrointestinal syndrome after exposure to radiation doses of >11 Gy at Chernobyl had diarrhea between 5–8 days postexposure; all these patients died.

NEUROVASCULAR SUBSYNDROME The neurovascular syndrome following whole-body radiation doses exceeding 10 Gy is a less well-defined, fatal subsyndrome despite full supportive care; the clinical course is more compressed than other radiation syndromes. Patients receiving supralethal radiation doses of >20–50 Gy usually die within 48 hours despite supportive treatment.[155] These patients develop severe prodromal symptoms (nausea, vomiting, diarrhea, anorexia) within minutes to a few hours postexposure; the clinical course rapidly progresses to confusion, ataxia, convulsions, coma, sweating, hypotension, and multiorgan failure similar to septic shock. Manifestations of both cardiovascular dysfunction (shock, myocardial necrosis) and CNS dysfunction (papilledema, ataxia, absent deep tendon reflexes, cerebral edema, convulsions) are present in patients exposed to supralethal radiation doses.[133]

CUTANEOUS SUBSYNDROME The skin is an important immunological and external barrier to pathogens; compromise of this barrier enhances the severity of other radiation-induced injuries including mortality.[156] The depth of dermal damage, amount of edema, and destruction of underlying soft tissue and bone from external radiation exposure is dependent on the absorbed radiation dose. Skin damage may occur with or without the clinical features of acute radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

syndrome, depending on the absorbed radiation dose. The sensitivity of skin structures to radiation-induced damage starts with the most vulnerable are sweat glands, epidermis, hair follicles, and sebaceous glands.[157] Cutaneous radiation injury ranges progressively over the course of weeks to months from erythema and hair loss to scaly flaking skin (dry desquamation), weeping skin (moist desquamation), dermal edema, hyperpigmentation, subepidermal vascular damage, skin ulceration, skin atrophy, dilation of small skin vessels, fibrosis, and necrosis. Higher absorbed radiation doses to the skin produce earlier transient erythema and tissue necrosis in weeks to months. Whole-body radiation exposure to 3 Gy produces erythema 2–3 weeks after exposure with temporary hair loss, whereas an acute dose of 6 Gy causes an initial erythema within 1–2 hours with more permanent hair loss. The erythema usually resolves after a few hours; reoccurrence of erythema develops several days to weeks postexposure. The estimated absorbed dose thresholds for the cutaneous radiation syndrome are 10 Gy for dry desquamation, 15 Gy for moist desquamation, >25 Gy for skin necrosis, and >40 Gy for muscle-bone necrosis. In contrast to thermal and chemical burns, the appearance of radiation-induced skin damage is delayed; erythema appearing within a few minutes suggests a chemical or thermal injury. Table 39.12 describes the various clinical features associated with the cutaneous subsyndrome.

Dry desquamation of skin occurs ~2–4 weeks after external skin exposure to 10 Gy; vesicles appear 2–8 weeks after exposure to >15 Gy. Compartment syndrome may develop following severe radiation exposures. Local skin exposure to external radiation doses of >40–50 Gy causes necrosis and deep ulcerations. Following exposure to very high external radiation doses, skin necrosis, soft tissue, and bones can continue to spread from the initial site. Skin ulcerations occur initially following high radiation doses; although these ulcers may heal, recurrence of the ulcers is common due to vascular damage and subsequent ischemia. These ulcers may persist for years. Pigmentation varies from patient to patient with the final appearance of skin pigmentation occurring ~1 year after radiation exposure. Sebaceous glands and hair follicles display similar radiosensitivity with destruction occurring following acute radiation doses of 12–16 Gy; hair on the scalp and beard are particularly sensitive to radiation, particularly in children.

In a 15-year follow-up study of 22 survivors of the Chernobyl accident with cutaneous subsyndrome, all patients developed varying features of xerosis, cutaneous telangiectasias, subungual splinter hemorrhages, hemangiomas, lymphangiomas, epidermal atrophy, disseminated keratoses, extensive dermal and subcutaneous fibrosis with partial ulcerations, and pigmentary changes including radiation lentigo.[159,160] One patient developed two basal cell carcinomas in the irradiated skin during the late part of the follow-up period. Other radiation-induced diseases in this case series included dry eye syndrome, xerostomia, radiation cataract, and increased FSH levels suggesting impaired fertility. Two patients died during the follow-up period from myelodysplastic syndrome and acute myelogenous leukemia.

Local Radiation Injury

The initial clinical signs of radiation and thermal burns (i.e., erythema, desquamation, vesiculation) are similar, except for the dose-dependent delayed onset of radiation burns as listed in Table 39.12. The risk of death

TABLE 39.12. Clinical presentation of mild to very severe cutaneous subsyndrome. (Adapted from Radiation Emergency Medical Management (REMM, US Department of Health & Human Services).[158]

Sign/Symptom	Range	Mild	Moderate	Severe	Very Severe
Alopecia	2 days–8 weeks	Thinning	Visible, patchy	Complete, reversible	Complete, irreversible
Altered sensation	Hours–days	Pruritus	Slight–intermittent pain	Moderate, persistent pain	Severe, persistent pain
Desquamation	5 days–8 weeks	Absent	Patchy, dry	Moist, patchy	Moist, confluent
Edema	5 days–8 weeks	Asymptomatic, present	Symptomatic	Secondary dysfunction	Total dysfunction
Erythema	Few hours–30 days	Minimal, transient	<10 cm^2 or <10% BSA	10–40% BSA	>40% BSA
Onycholysis	2 days–8 weeks	Absent	Partial	Partial	Complete
Ulceration/Necrosis	5 days–8 weeks	Epidermis	Dermal	Subcutaneous	Deep tissue involvement
Vesiculation	5 days–8 weeks	absent–rare	Rare, hemorrhagic	Sterile bullae	Hemorrhagic bullae

Abbreviation: BSA = body surface area.

following local skin irradiation is relatively small and dependent on burn depth reflecting the rapid decline in radiation dose rate with distance from the source. An estimated radiation dose of ~10,000 Gy to the legs resulted in bilateral leg amputations; however, initial pain or other symptoms of the acute radiation syndrome did not develop.[161] A 35-year follow-up study of four men irradiated with a skin dose of 200 Gy revealed no evidence of cancer, partly reflecting the reduction in the cancer incidence dose-response curve at very high doses.[162] At Chernobyl, radiation burns from β-irradiation were an important determinant of the prognosis for patients with acute radiation syndrome. The combination of radiation burns over 50% of the body and the hematopoietic system was inevitably fatal.[163]

Skin

Deep, localized skin exposure typically occurs while handling highly radioactive sources rather than from nuclear incidents. Frequently, these patients present weeks after exposure when edema, erythema, hyperpigmentation, desquamation, vesiculation, and pain occur. Radiation damage to the germinal cells in the basal layer of the epidermis produces four dose-dependent clinical stages characterized by: 1) transient erythematous reaction (an inflammatory response appearing within a few hours and disappearing within several days), 2) delayed main erythematous reaction with dry or wet desquamation (vesicles, bullae) depending on radiation dose, 3) late erythematous phase associated with dermal ischemia or necrosis after 8–16 weeks, and 4) delayed biphasic skin damage manifest by dermal atrophy after 26 weeks and skin necrosis and/or telangiectasias after 1 year.[164] An acute exposure to high-LET and neutron radiation estimated at 12.5 Gy produced the peak main erythematous reaction ~30 days postexposure.[165] Although the severity of the early erythematous reaction depends on total absorbed dose, dose fractionation, and the relative biological effectiveness of the radiation, the rate of radiation-induced skin damage depends on the regeneration of the basal cells in the epidermis and/or the clonogenic cells in the hair follicle canals rather than the dose.[166] Except for superficial injuries, the skin lesions usually evolve slowly, heal poorly, and recur sometimes years after the initial radiation exposure, as displayed in Table 39.13.

The presence of multiple/blunt trauma, steam burns, crush injuries, electrical injuries, and heat exhaustion complicates the initial evaluation for evidence of radiation-induced skin damage and the prodromal phase of the acute radiation syndrome. In the absence of these injuries, the presence of erythema within several hours suggests exposure to >2–8 Gy; however, this sign is neither sensitive nor specific. The intense heat of superheated steam produces blanching of the skin and third-degree burns that may be confused with radiation burns. Initially, radiation-induced burns are usually painless in contrast to thermal burns. Wet desquamation and second-degree thermal burns appear similar; the onset of these lesions at ~2–6 weeks marks the time when pain begins dominating the clinical picture.[167] Necrosis begins with ulcerations of variable depth ~2 weeks to several months postexposure following radiation doses of >25 Gy. The initial phase of dermal thinning at 16–26 weeks is associated with necrosis following exposure to high radiation dose. By 1 year, skin healing is usually complete with sequelae including hyperpigmentation, depigmentation, dry/atrophic skin susceptible to trauma, and telangiectasia. Healed radiation wounds have less strength than normal skin.

TABLE 39.13. Dermatological changes associated with acute absorbed radiation doses (Gy). (Adapted from Mettler and Voelz).[118]

Dose	Onset After Exposure	Clinical Features
3–4 Gy	2–3 weeks	Hair loss
10–15 Gy	Few hours (high dose) to 3 weeks (low dose)	Erythema with subsequent dry desquamation[a]
20 Gy	4–6 weeks	Moist desquamation (vesicles → bullae) with potential for ulceration
25 Gy		Ulceration with slow healing[b]
30–50 Gy	3 weeks	Blistering, necrosis
100 Gy	1–2 weeks	Blistering, necrosis

[a] Dose-dependent; [b] Skin necrosis and ulcerations may occur from ~16 weeks to >1 year at this radiation dose; the onset of necrosis and ulcerations occurs more quickly at higher radiation doses.

Dermal radiosensitivity depends, in part, on the depth of the basal layer; the depth varies with the location of the skin on the body. The thinnest areas (20–60 μm) exist on the trunk and face. Substantially more radiation damage may occur in these areas when the radiation dose includes low-energy photons and α- or β-emitters.[168] High doses (>100 Gy) of these types of radiation may produce direct cell death in the skin with clinical signs of acute epidermal necrosis occurring as soon as 2 weeks after exposure.

Muscle and Bone

Muscle, bone, and cartilage are relatively radioresistant; however, children in puberty or below the age of 6 years are less radioresistant than other children and adults.[169] In these young children, 10 Gy produces

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. mild boney changes, whereas 10–20 Gy may cause asymmetric bone growth including spinal deformity, slipped capital epiphyses, aseptic necrosis of the hip, and hypoplasia of exposed bones.[170] Decreased bone activity can occur 4–19 months after fractionated doses of 20 Gy; necrosis of the bone results from fractionated doses exceeding 45 Gy. Osteonecrosis is rare in adults; complications include susceptibility to fractures from osteonecrosis with poor bone healing and reduced resistance to infection. Separating radiation-induced osteonecrosis from osteomyelitis is frequently difficult. The radiosensitivity of cartilage and bone is similar. Animal studies indicate muscle is extremely radioresistant with doses exceeding 500 Gy required to produce necrosis.[171] Atrophy and fibrosis of the muscle may occur from vascular insufficiency at lower fractionated doses (e.g., <50 Gy).[172]

Mucosal Surfaces

Alteration in the mucosa occurs in the pharynx, mouth, tonsils, nose, and tongue within a few days to 5 weeks after radiation exposure depending on the dose. Hyperemia of the oral cavity and pharyngeal edema develop within several days of exposure to 5–10 Gy followed by bleeding, ulceration, and necrosis.

Hair

Temporary hair loss (epilation) occurs at doses of >3–5 Gy beginning as early as 7 days after exposure; epilation typically starts 18–30 days postexposure. Hair loss may occur in the absence of radiation-induced erythema. An acute radiation dose of 7 Gy may produce permanent hair loss beginning 3 weeks after exposure.[123] Children are more susceptible to epilation than adults; the scalp and beard are the most sensitive portions of the body to hair loss after irradiation. In the range of 0.5–5 Gy, animal studies document a dose-related decrease in the diameter of the hair shaft.[173] The regrown hair in humans typically is slower-growing and finer than the original hair; occasionally, the color and curliness of the replacement hair differ from the original hair.

Chronic Sequelae

Deterministic radiation effects (tissue reactions) produce dose-dependent cell destruction, resulting in hypothyroidism, cataracts, skin atrophy, sterility, growth retardation, fibrosis, and chronic ulcerations. These biological effects occur uniformly in individuals exposed to identical radiation doses exceeding the threshold for the specific effect. The incidence and severity of these effects increase with increasing radiation doses. A follow-up Life Span Study of the cohort of atomic bomb survivors suggests acute radiation exposure exceeding 0.5–0.75 Sv may increase noncancer mortality for heart disease, stroke, digestive diseases, and respiratory diseases with an excess relative risk for overall noncancer and heart disease mortality of 14%/Sv (90% CI: 8–20%/Sv) and 17%/Sv (90% CI: 8–26%/Sv), respectively.[145] This study did not detect excess noncancer mortality in victims receiving <0.5 Sv. Studies of other radiation-exposed cohorts (e.g., patients) have not demonstrated similar excess relative risks of noncancer mortality, except for cardiovascular mortality; however, the risks per unit dose in these epidemiological studies vary over two orders of magnitude.[174] Consequently, the presence of confounding variables may account for the increased excess relative risk of cardiovascular mortality reported in the positive studies. The lungs are highly radiosensitive, particularly to chronic inflammation, fibrosis, and cancer. Inflammatory pneumonitis develops within 2–4 months and fibrosis ~4–6 months after radiation exposure, manifested by interstitial edema, inflammatory infiltrate, and epithelial loss.[175]

Cataracts

The latent period for radiation-induced cataracts is dose-dependent and highly variable with a range of 0.5–35 years and a mean of 2–3 years.[176] The dose-dependent occurrence of mild forms of lenticular opacities without visual impairment appeared in Japanese survivors at radiation doses of 0.6–1.5 Gy.[177] The incidence and severity of cataracts also increased with estimated dose in survivors at Hiroshima and Nagasaki.[178] The threshold for single exposures to γ-rays or X-rays following the therapeutic use is 2 Gy for single radiation doses and 5 Gy for fractionated radiation.[179] Almost all patients exposed to acute radiation doses of >7.5–8 Gy will develop cataracts. Fractionation doubles the threshold radiation level for cataracts. Confounding factors for cataract development include age, corticosteroid medications, diabetes mellitus, genetic predisposition, sex, smoking, and UV exposure.[180]

Radiation-induced cataracts are typically posterior subcapsular cataracts and occasionally involve cortical opacities; however, nuclear opacities are not usually associated with radiation injuries. A study of 873 Japanese atomic bomb survivors demonstrated an odds ratio for posterior subcapsular cataracts following 1-Sv exposure of 1.41 (95% CI: 1.21–1.64) and 1.29 for cortical cataracts (95% CI: 1.12–1.49) using the Lens Opacity Classification System II.[181] The odds ratio for nuclear cataracts in a survivor exposed to 1 Sv was not statistically different than the control group

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. (<0.005 Sv) after adjustment for city, sex, age at the time of the bombings, and smoking. In contrast to senile cataracts that usually begin in the anterior pole of the eye, radiation-induced cataracts begin in the posterior pole of the eye. In a study of 8,607 Chernobyl cleanup workers with follow-up of 12–14 years, the prevalence odds ratio for 1 Sv and stage 1 posterior subcapsular cataracts was 1.52 (95% CI: 1.01–2.00).[182] The maximum likelihood central estimates of the dose threshold for stage posterior subcapsular cataracts were 0.35 Sv (95% CI: 0.19–0.66 Sv). The radiation exposure of 77% of the workers was below 0.2 Sv. These cataracts gradually enlarge, extending into the anterior pole. The classic presentation of radiation-induced cataracts is a localized lenticular opacity on the inner surface of the posterior polar capsule, with either punctate or aggregations of opacities in the subcapsular cortical layer of the posterior polar region.[183] These lenticular opacities increase slowly, and then their development typically stops. These opacities rarely progress following the cessation of radiation exposure.

Rodent studies suggest estrogen may accelerate the progression of radiation-induced lens opacification.[184] In these rodent studies, hormone supplementation experiments suggest estrogen is responsible for the enhancement of radiation-induced cataract formation by ovarian hormones; however, epidemiology studies associating female sex hormones with cataract formation are conflicting.[185]

Retinopathy

Radiation retinopathy developed in most survivors of the atomic bombings who received high radiation doses.[186] The ocular manifestations of radiation retinopathy and diabetic retinopathy are similar, including macular edema, microaneurysms, retinal hemorrhages, poor capillary perfusion, and nerve fiber layer infarcts. Substantial variation in the susceptibility to radiation-induced retinopathy occurs with a few patients developing radiation retinopathy below the currently accepted upper safe limit of a fractionated dose of 35 Gy.[187] Susceptible individuals include diabetic, hypertensive, and chemotherapy-treated patients.[188]

Carcinogenesis

The International Agency for Research on Cancer (IARC)[189] and the US National Toxicology Program[190] classify X- and γ-rays as Group 1 (human) carcinogens. Analysis of data from the Life Span Study of atomic bomb survivors indicates X-ray and γ-ray radiation causes cancer of the bladder, bone, brain and CNS, premenopausal female breast,[191] colon, esophagus, leukemia (excluding chronic lymphocytic leukemia),[192] kidney, lung, salivary gland, skin (basal cell), stomach, and thyroid (children, adult females).[30,193] These data are also suggestive of a positive association between these radiation types and cancer of the rectum, liver, non-Hodgkin lymphoma, multiple myeloma, ovary, pancreas, and prostate. In occupational studies, these cancers occur primarily in subcohorts with high-dose radiation exposure during early years of employment.[194] Cancers of the bone, soft tissue, skin, rectum, and soft tissue require relatively high doses, whereas some cancers (gallbladder, chronic lymphocytic leukemia, Hodgkin lymphoma, uterus) are not causally associated with X- or γ-radiation.[189] Only a small number of individuals irradiated with the same dose will develop cancer similar to the distribution of other stochastic effects including teratogenesis (predominantly severe mental retardation) and genetic abnormalities.[195] The cancer incidence increases with the radiation dose. The most sensitive tissues to radiation-induced cancer in the atomic bomb survivors were bone marrow, thyroid, and female breast.[9] Significant increases in mortality also occurred from cancers of the stomach, colon, bladder, esophagus, and lung.

Latent Period

Cancer is a multistage process involving: 1) *initiation* of irreversible DNA changes to create a cell with neoplastic proliferative potential, 2) *promotion* of initiated preneoplastic cells into expanded clones, 3) *neoplastic conversion* transforming preneoplastic cells into an autonomous variant able to proliferate, and 4) *malignant progression* of cells and progeny to accumulate changes allowing unrestrained growth, invasion of normal tissues, and metastasize to distant sites. A substantial latent period occurs between radiation-induced cell initiation and the clinical appearance of the tumor.

The latent period between radiation exposure and the clinical expression of the cancer depends on age and cancer site, as demonstrated in the Life Span Study of atomic bomb survivors under the age of 10 years at the time of exposure. In epidemiology studies of malignant breast tumors in atomic bomb survivors, female Japanese children exposed before 9 years of age had a longer latency period than Japanese women exposed during their twenties.[196] The increased leukemia incidence first occurred ~2–3 years after the bombing with peak incidence emerging 6–8 years after the bombing.[197] The minimal latency periods for bone cancer are 3–4 years and 4–5 years for thyroid cancer.[123,198] Although the minimum latent period for other solid

Stomach	14
Thyroid	20

[a] Excludes chronic lymphocytic leukemia.

tumors is ~5–10 years, the mean latent period for solid tumors is typically 20–30 years.[118] The mean latent period for all tumors in survivors of Hiroshima and Nagasaki averaged ~15 years.[199] Table 39.14 lists the estimated mean latent period for the development of leukemia and solid tumors after acute whole-body radiation exposure.

Approximately 17% of radiation-induced leukemias occurred 22–33 years after the bombing.[200] For breast cancer, both age at exposure and age attained were important modifiers of the dose response.[201] Exposure of females before age 20 was associated with higher dose-specific excess relative risk of breast cancer compared with exposure at older ages; there was no consistent variation by exposure age for ages under 20. The relative risk declined with increasing age; the largest drop occurred at ~35 years of age.

Hiroshima and Nagasaki Survivors

Leukemia

Leukemia is the most common cancer detected in survivors of the atomic bombings in Hiroshima and Nagasaki; leukemia accounted for $\sim^1/_3$ of the initial cases of excess cancers.[202] The clinical, pathological, and genetic manifestations of radiation-induced leukemia and leukemia from other etiologies are similar, including cytotoxic drug-induced leukemias.[203] All types of leukemia appeared following radiation exposure except chronic lymphocytic leukemia.[204] The acute forms of leukemia account for the increased risk in children soon after the bombing, whereas adults also develop an increased risk for chronic myelogenous leukemia. Although the risk of developing leukemia decreased after 10 years, the risk did not return to baseline levels seen in controls 30 years after the bombing.[205]

The risk of developing leukemia varies with the radiation dose, age at radiation exposure, type of leukemia, and time elapsed since exposure. Most cases of radiation-induced leukemias demonstrate cytogenic abnormalities of chromosomes 5 and 7 with similar point mutations and base substitutions in the *N*- and *K-RAS* oncogene sequences.[206,207] Acute lymphoblastic leukemia is the common subtype in children, whereas acute and chronic myelogenous leukemias are the common subtypes in elderly patients.

Radiation from the A-bomb produced excess leukemias sooner than other radiation-induced cancers, particularly in children. In the Life Span Study cohort of 49,204 Japanese survivors, 204 leukemia-related deaths occurred from 1950–2000 with 94 deaths (46%) attributed to bone marrow doses of ≥0.005 Gy based on DS86 dosimetry.[208] Although the relative risk of radiation-induced leukemia is high, the absolute number of leukemia cases among survivors is relatively small because leukemia is a rare disease in the Japanese population. The updated DS02 dosimetry estimates decreased the curvilinear dose-response for leukemia by ~8% due to increased γ-ray dose estimates; however, the shape of the curve, estimated age-time patterns, and sex differences remain similar.[209] Table 39.15 displays the observed, estimated excess, and attributable risk associated with weighted bone marrow doses ranging from 0.005 Gy to over 2 Gy based on DS86 dosimetry. A few new cases of leukemia are occurring in this cohort currently.

Thyroid Cancer

Thyroid cancer was the first radiation-induced solid tumor recognized in Japanese survivors after the bombings in Hiroshima and Nagasaki; however, the mortality rates were not significantly increased among survivors because of the low mortality associated with thyroid cancer. These studies demonstrated a concave dose-response curve for the development of solid nodules in the Japanese cohort of atomic bomb survivors. Most,[210] but not all studies,[211] failed to detect a statistically significant relationship between radiation and the incidence of antibody-positive or antibody-negative hypothyroidism (autoimmune hypothyroidism). The common pathological types of radiation-induced thyroid cancer are papillary adenomas and carcinomas. Females and young children display a greater risk (2–4-fold for females) of developing thyroid cancer following irradiation than men.

TABLE 39.15. Attributed leukemia-related mortality in the Life Span Study cohort of Japanese atomic bomb survivors 1950–2000 using DS86 dosimetry. (Adapted from RERF).[208]

Weighted Bone Marrow Dose (Gy)	Persons	Observed Deaths	Estimated Excess Deaths	Attributable Risk
<0.005	37,407	92	—	—
0.005–0.1	30,387	69	4	6%
0.1–0.2	5,841	14	5	36%
0.2–0.5	6,304	27	10	37%
0.5–1.0	3,963	30	19	63%
1.0–2.0	1,972	39	28	72%
>2	737	25	28	100%
Total	49,204	296	94	46%

Solid Tumors

Radiation-induced cancers typically become clinically apparent only after the atomic bomb survivors attain the age at which the specific cancers usually appear. In the cohort of Japanese survivors, ~260 nonleukemia-related cancer deaths from 1950–1985 are attributed to radiation doses of >0.01 Gy.[9] This number of deaths represents ~8% of the total deaths from cancers other than leukemia. The cancer rates in some solid tumors (e.g., pancreas, prostate, rectum, uterus) and chronic lymphocytic leukemia in the Life Span Study were similar in exposed and unexposed survivors.[212]

Environment Exposure

Most case-control studies of populations inhabiting areas with high natural radiation levels do not consistently demonstrate a statistically increased cancer incidence including residential radon studies.[9,213] However, some studies of natural radiation are positive. An increased incidence of thyroid nodules and chromosomal aberrations in peripheral lymphocytes occurred in a Chinese population exposed to high levels of background radiation (3–4 mSv γ-radiation/year).[10] Pooled data from two Chinese case-control studies of residential radon detected dose-related increases in the odds ratios of lung cancer mortality, particularly in residents inhabiting their home for over 30 years (OR = 1.33 at 100 Bq/m^3, 95% CI: 1.07–1.91).[214] Examination of cohorts exposed to highly contaminated releases from the Chernobyl accident indicates an excess incidence of thyroid cancer consistent with estimates of other populations exposed to radiation, primarily in children. The epidemiological evidence linking leukemia and nonthyroid solid cancers with environmental radiation exposures is inconclusive.

Nuclear Facilities

Most studies of various populations living adjacent to nuclear facilities involve thyroid disease and leukemia. Maternal radiation exposure was not related to the risk of developing central nervous system tumors in a case-control study of 338 children; the association with paternal exposure was inconsistent.[215]

Accidental Releases An increased rate of thyroid cancer occurred after the accidental nuclear release from the Chernobyl reactor; aging of the cohort and improved case ascertainment do not account for this increase with the estimated risks consistent with other radiation-exposed populations.[207] Iodine deficiency is a modifying factor in thyroid cancer risk. The current evidence of other cancer outcomes in this cohort is limited, with little indication of an increased risk of leukemia following exposure in fetuses, children, or adults. The most common late effect from exposure to thyroid radiation is the development of thyroid nodules; however, imprecise screening methods for thyroid nodules complicate the interpretation of epidemiology studies including the determination of nodule size and the occurrence of preexposure indolent nodules.[216] Although the mean accumulated thyroid dose from exposure to fallout from Chernobyl was 0.6–1.9 Gy in children and 0.2–0.4 Gy in adults, no significant increase in the incidence of thyroid nodules was detected within the first 5 years postexposure.[217] Current data do not support a causal relationship between increased childhood leukemia and releases from radioactive waste or the 1979 accident at the Three Mile Island nuclear power plant in Pennsylvania.[55] Retrospective analysis of the Pennsylvania Cancer Registry Dataset did not detect an increased thyroid cancer incidence in Dauphin County, where the power plant is located.[218] Nearby York County demonstrated a trend toward increasing thyroid cancer incidence beginning in 1995, ~15 years after the TMI accident,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

whereas nearby Lancaster County showed a significant increase in thyroid cancer incidence beginning in 1990.

Epidemiological data from studies of residents in contaminated regions of Belarus and the Russian Federation exposed to fallout from Chernobyl indicate a dose-dependent increase in the incidence of thyroid cancer, primarily in children. The main route of exposure for these children was the ingestion of ^{131}I-contaminated cows' milk and food. The most contaminated areas occurred in Belarus (e.g., Gomel) with several thousand children receiving a cumulative radiation dose of 2 Gy;[219] the increased incidence of thyroid cancer began ~5 years after the Chernobyl release, persisting into young adulthood consistent with studies of other radiation incidents.[220] In a population-based case-control study of 276 cases of thyroid cancer and 1,300 matched controls all aged <15 years living in contaminated areas of Ukraine and Russia after the Chernobyl accident, the estimated radiation dose and thyroid cancer risk demonstrated a significant dose-response relationship ($P < 0.001$). The odds ratio for a cumulative 1-Gy exposure varied from 5.5 (95% CI: 3.1–9.5) to 8.4 (95% CI: 4.1–17.3), depending on the applied risk model.[221] The risk of thyroid cancer was higher in iodine-deficient areas (RR = 3.2, 95% CI: 1.9–5.5) and lower in children receiving potassium iodide supplementation (RR = 0.34, 95% CI: 0.1–0.9). There is no convincing evidence of significant excess incidences of leukemia or other solid tumors following exposure to the Chernobyl release.

The radiation doses from the Fukushima Daiichi Nuclear Power Plant accident were extremely low; however, the relatively short physical half-life of ^{131}I complicates the determination of the actual dose. Most of the surrounding residents (i.e., 99.9%) probably received <1 mSv/year.[222] In a study of 300,476 Fukushima residents ≤18 years of age at the time of the accident, no thyroid cancers were attributed to the radiation exposure during screening four years after the incident.[223] The typical latency period for thyroid cancer is 4–5 years.

Nearby Residents

Thyroid Disease Evidence for an association between an elevated thyroid cancer risk and exposure to radiation from nuclear facilities is limited. Over 25,000 residents living near the Techa River in the southern Urals of the Russian Federation were exposed to external (γ-rays) and internal (^{137}Cs, ^{106}Ru, ^{90}Sr, ^{95}Zr) radiation released into the Techa River from the nearby Mayak plutonium production complex, predominately during the early 1950s. In a Russian study of 72,185 residents of Ozyorsk for at least 1 year while under the age of 15 years and exposed to fallout from Mayak Production Association (Mayak PA), the thyroid cancer incidence was elevated ~3–4 times the Russian rate and 1.5–2 times the local Chelyabinsk Oblast rates.[224] The Hanford Thyroid Disease Study did not detect an increase in thyroid cancer or other thyroid diseases with increasing thyroid radiation doses from Hanford facility ^{131}I releases.[225]

Leukemia Although studies of residents near nuclear installations have not demonstrated increased overall cancer mortality,[226] some ecological studies from the United Kingdom suggest the possibility of excess leukemia near some nuclear facilities including children near the Sellafield plant in Seascale, Cumbria (6–8-fold), Dounreay (5-fold),[227] Aldermaston (1.4-fold),[228] and Hinkley Point (1.8-fold).[229] Other studies of populations near nuclear facilities in the United States,[230] Scotland,[231] and La Hague, Normandy[232] did not detect statistically significant trends in mortality from childhood leukemia. Although these studies did not possess sufficient power to exclude the presence of an effect, they indicate the 6- to 8-fold increase in leukemia risk detected in the Sellafield plant in Seascale is probably an overestimate. These ecological studies of populations living near nuclear facilities and other potential sources of radiation do not contain *individual* estimates of radiation doses.

This increased leukemia incidence at these British facilities cannot be explained by the absorbed radiation dose from nuclear waste because the amount of radiation varies 1,000-fold between these four facilities, whereas the relative risk of leukemia fluctuates by less than 10-fold.[233] A case-control study of cases of childhood leukemia reported between 1950–1985 near the Sellafield plant suggests the effect of ionizing radiation on the fathers working at the nuclear facility may affect the incidence of leukemia and non-Hodgkin lymphoma in their offspring.[234] The excess leukemia cases occurred in Cumbrian children born in the area near the Sellafield plant rather than children moving to the area after birth. Data from parental questionnaires did not suggest an association between leukemia and radionuclides discharged from the Sellafield plant. This study did not detect any genetic abnormalities other than increased leukemia incidence. Although the number of leukemia cases was small, the effect was large with an exposure to radiation doses of >100 mSv associated with a 6–8-fold increase in the risk of developing leukemia in offspring. This magnitude of leukemia risk is inconsistent with data from the atomic bomb survivors because **no** increase in leukemia occurred in the cohort of 7,400 Japanese offspring of fathers exposed to radiation doses (0.3–0.6 mSv) four times greater than

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the fractionated radiation dose received by the workers at Sellafield. The relative risk of developing leukemia was <1 when the paternal dose was <0.1 mSv.

Interpretation of the significance of geographic clusters of disease (i.e., leukemia incidence at Sellafield) is limited because the small number of cases increases the sensitivity of the data to diagnostic, reporting, and classification biases.[235] Confounding from infectious agents,[236] genetic effects, chemical mutagens, drugs, and the ingestion of α-emitting radionuclides may influence the risk of developing leukemia.[233,237] A causal association between childhood leukemia and radiation exposure in the communities surrounding these nuclear facilities remains controversial.[238,239] The importance of the Seascale study lies in the strength of the association between paternal ionizing radiation and childhood leukemia. The increased risk detected by this study probably did not result from chance, but the etiology of the increased incidence of leukemia remains unknown;[240] the values published in this study depend on four cases of paternal exposure of 0.1–0.2 mSv and imply the sensitivity of the human genome to heritable mutations is several orders of magnitude greater than data from animal experiments and the atomic bomb survivor cohort.[241] The statistical significance of the association between childhood leukemia and paternal irradiation was relatively weak because the *P* value was 0.05 rather than 0.01 typically used for multiple comparisons.

A case-control study of children in Caithness near the Dounreay nuclear installation did not support an association between paternal exposure to external ionizing radiation before conception and childhood leukemia or non-Hodgkin lymphoma,[242] whereas a case-control study of 54 children with leukemia and non-Hodgkin lymphoma in West Berkshire and North Hampshire Districts found a statistically nonsignificant elevation (RR = 2.2, 95% CI: 0.6–6.9) in the number of children with fathers who were employed in the nuclear industry.[243]

Three case-control studies of populations residing near nuclear facilities did not demonstrate an increased cancer risk in the exposed group. The studies of residents near a French and a Scottish nuclear facility examined the risk of leukemia associated with environmental radiation exposures as determined by employment records and parental questionnaires.[242,244] Although both studies suggested an association between playing on beaches near nuclear facilities and leukemia, the small number of cases, potential systemic bias, and multiple hypothesis testing limit conclusions regarding causality.

Weapons Testing

Thyroid Cancer High radiation doses are a recognized cause of benign thyroid nodules and thyroid cancer. From June 1946 to August 1958, The US Department of Defense and the US Atomic Energy Commission conducted 66 nuclear weapons tests in the Northern Marshall Islands with 20 resulting in measurable fallout on one or more inhabited atolls. The largest aboveground thermonuclear test ever conducted by the United States was the Castle BRAVO test on March 1, 1954; the yield was 1,000 times greater than the Hiroshima atomic bomb. An unexpected wind shift resulted in the deposition of high levels of radioactive material on Rongelap and Utirik atolls. On March 3, 1954, inhabitants of these atolls were evacuated with the residents later returning to Utirik in June 1954 and to Rongelap in June 1957.[40] Adults of the northern Marshall Islands received an estimated external dose ranging from hundreds of mGy to over 1,000 mGy compared with 22–59 mGy for midlatitude atolls and 5–12 mGy for the southern atolls (control group).[245] Estimated adult internal thyroid doses were 760 mGy (Utirik community) and 7,600 mGy (Rongelap Island community), with young children on Rongelap during the Castle BRAVO test receiving ~3-fold the adult dose. Based on these doses, ~20% of the thyroid cancers and ~5% of leukemias were attributed to the fallout with a projected 170 lifetime excess cancers compared with ~10,600 spontaneous cancers during this time.[246] Although the prevalence of thyroid cancer in residents born before the Castle BRAVO test was elevated, the difference between the quartiles of exposure was not statistically significant. From 1954–1985, thyroid nodules appeared in 63% of children and 33% of adults living on the most heavily exposed atoll in Pacific test sites.[247] Similar excess incidences of thyroid nodules (i.e., estimated risk of 1,100 excess cases/10^6 person years-Gy) occurred in the inhabitants of other atolls in the Marshall Islands.[248] A cohort study of 3,122 schoolchildren exposed to an estimated mean thyroid dose of 170 mGy (range, 0–4,600 mGy) from Nevada Test Site fallout of 1951–1958 demonstrated a statistically significant excess of thyroid neoplasms (benign and malignant).[249] A relative risk of 3.4 occurred in subjects exposed to radiation doses of >400 mGy with an excess relative risk of 0.7% per mGy; although the dose-response slopes were positive, the dose-response was not statistically significant. In a case-control study comparing the risks of thyroid cancer mortality and incidence of residents near Nevada nuclear testing sites with US rates, the study suggested an increased thyroid cancer mortality for the 1950–1959 birth cohort (ERR = 12.0, 95% CI = 2.8–31); however, wide confidence intervals, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. absence of a dose-response, and the generally negative results including thyroid cancer incidence rates limit conclusions regarding causality.

Leukemia In the latter part of the 1970s, several studies of residents of Utah and neighboring states downwind of the Nevada Test Site and test participants suggested an increased cancer incidence following radiation exposures of <50 mSv, primarily leukemia. The BEIR V Committee concluded that the most likely explanation for these excess observed cases of leukemia is a random overestimate of the risk coefficients.[9] Although the number of cases of leukemia is small, some case-control studies suggest a weak association between exposure to fallout from nuclear testing and leukemia incidents.[250,251] However, estimates of the number of cases attributable to these regions are small and lack a statistically significant association between estimated red bone marrow dose and leukemia mortality and incidence.

Several ecological studies of populations exposed to fallout from nuclear testing did not demonstrate statistically significant increases in childhood or adult leukemia. In an observational study of the leukemia incidence rates in Nordic children exposed to fallout from Soviet nuclear tests, no consistent, dose-related increase in leukemia risks during the first 15 years of life was detected in children born during the years of the highest fallout.[252] During the early, high-fallout time, the average estimated dose equivalent to fetal red bone marrow was ~0.14 mSv with little evidence of increased leukemia risk during the first 15 years of life (RR = 1.07, 95% CI: 1.0–1.4). An ecological study of ^{131}I exposure from nuclear testing in Nevada in the 1950s did not demonstrate a statistically significant increase in leukemia incidence during the first 15 years after fetal exposure when comparing cumulative high- (≥ 90 mGy) and low- (0–39.9 mGy) groups.[253] The relative risk for the high-dose group was 0.97 (95% CI: 0.91–1.03) with the low-dose group being the referent group. In a British study of 21,357 servicemen exposed to fallout during UK atmospheric nuclear weapons testing in the Pacific Ocean followed from 1952–1998, mortality and cancer incidence were similar between the exposed group and a control group of 22,333 unexposed servicemen based on film badge readings and potential exposure from job duty. Of the 4,808 men wearing film badges, 1,776 had detectable radiation doses with a mean of 9 mSv. The study suggested the possibility of a small increased leukemia incidence in the exposed group (RR = 1.41, 90% CI: 0.96–2.09; $n = 67$) excluding chronic lymphocytic leukemia (CLL) compared with controls that had leukemia incidence and mortality rates below the national averages. The difference between the two groups was not statistically significant. The relative risk for leukemia mortality in the exposed group excluding CLL was 1.83 (90% CI: 1.15–2.93).

Occupational Exposure

Epidemiological studies of occupational cohorts exposed to radiation complement the relative risks of adverse effects detected in other populations (e.g., Japanese A-bomb survivors), particularly in the low-dose and low-dose rate ranges (100–200 mGy); however, these studies frequently do not involve individual exposure data, resulting in significant uncertainties with variable estimates of cancer incidence, mortality, and large confidence intervals. These occupational cohorts include medical staff (e.g., radiologists), Chernobyl cleanup workers (liquidators), nuclear industry workers, and nuclear weapons test participants.[254] In 1944, the large excess of leukemia among US radiologists provided the first published evidence of the stochastic effects of low LET-radiation.[255] A mortality study compared the risk of death from acute myeloid leukemia and/or myelodysplastic syndrome in 43,763 radiologists (20% women) and a comparison group of 64,990 psychiatrists (27% women) graduating from medical school 1916–2006.[256] The mortality risk was elevated (RR = 1.62, 95% CI: 1.05–2.50) in radiologists graduating before 1940; however, the study did not detect excess mortality in radiologists graduating more recently. The authors opined that increased radiation protection and/or lifestyle changes possibly accounted for the difference in mortality between newer and older medical school radiology graduates.

In a study of the Rocketdyne cohort of 5,801 workers involved in radiation activities with exposure primarily to radionuclides, the SMRs for all cancers (0.88, 95% CI: 0.81–0.95), lung cancer (0.87, 95% CI: 0.76–1.00), and leukemia other than chronic lymphocytic leukemia (1.04, 95% CI: 0.67–1.53) were not statistically different than the general population.[257] There were no significant dose-response trends for any cancer as detected by Cox regression analyses. The mean cumulative dose of external radiation was relatively low (13.5 mSv) with a range up to 1,000 mSv as determined by a monitoring program for 2,232 workers. The estimated relative risk for all solid cancers for exposure to 100 mSv was 0.98 (95% CI: 0.82–1.17) compared with 1.06 (95% CI: 0.50–2.23) for all leukemias other than chronic lymphocytic leukemia.

The average cumulative whole-body exposure of monitored workers was 124 mSv at Sellafield, 32.4 mSv at the UK Atomic Energy Authority, and 7.8 mSv at

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the Atomic Weapons Establishment. Studies of cohorts from the Atomic Weapons Establishment[258] and Oak Ridge National Laboratory[259] detected a statistically significant positive correlation between radiation exposure and cancer mortality, primarily from an increased lung cancer mortality. Many workers at Sellafield accumulated radiation exposures of >50 mSv;[260] cancer mortality (SMR = 96, 95% CI: 90–103) was 4% below the England and Wales national rates and similar to data from the local UK county of Cumbria rates (SMR = 100, 95% CI: 94–107). A positive correlation occurred between leukemia incidence and cumulative radiation dose in exposed workers (2-year lag, $P = 0.009$). Mortality rates were significantly elevated above national rates for thyroid cancer (6 observed, 1.8 expected; $P = 0.01$). The estimated risk estimate for leukemia was four times higher than that for adult atomic bomb survivors with a confidence interval ranging up to ~20 times the estimate risk for atomic bomb survivors consistent with significant uncertainties regarding dose estimation. Leukemia-related deaths were not statistically significantly increased in the HARDTACK study of 1,010 navy veterans exposed to 5 rem for 1 year and unexposed navy controls (adjusted RR = 1.51, 95% CI: 0.23–9.69; $n = 3$); however, mortality from lymphopoietic cancer was significantly increased (RR = 6.44, 95% CI 1.96–21.24, $n = 6$).[261] The lack of increased mortality from cancers typically associated with radiation exposure, large confidence limits, and small case numbers suggest the presence of causal factor beside radiation.

Examination of 95,217 workers in the National Registry for Radiation Workers also demonstrated evidence for an association between radiation exposure and mortality from leukemia and multiple myeloma.[262] A statistically significant and dose-related increase in mortality from multiple myeloma also occurred in the cohort from Hanford;[263] however, this correlation ($P = 0.10$) was weaker in an updated analysis of this cohort.[264] Updated analyses of combined mortality data on workers at Hanford, Oak Ridge National Laboratory, and Rocky Flats Weapons Plant did not support a positive correlation between radiation exposure at Hanford and elevated risk of death from multiple myeloma.[265] The increased cancer risks with increasing age at Hanford and Oak Ridge indicated the possibility of significant dose uncertainties and the need for caution in interpreting the data.

The Atomic Weapons Establishment study reported excess prostate cancer deaths in exposed workers; however, internal contamination from radionuclides (e.g., tritium) accounted for at least some of the association. The elevated prostate cancer rates in the early Oak Ridge National Laboratory and the British Nuclear Fuels studies were not statistically significant or dose-related.[260] The lack of an association between radiation exposure and prostatic cancer in the Japanese atomic bomb survivors and the National Registry for Radiation Workers[262] suggests this association is coincidental.

In Utero Exposure

Although the risk of childhood cancer increases following exposure of the fetus or embryo to high radiation doses (i.e., >0.5 Gy), the risk of cancer in offspring following low radiation doses (i.e., <0.1 Gy) remains controversial.[266] Increased cancer mortality during the first year of life and after 9 years of age occurred in Japanese atomic bomb survivors exposed to radiation *in utero*;[267] however, only perinatal deaths correlated to the radiation dose received. The initial follow-up of the cohort of survivors of the atomic bomb irradiated *in utero* did not demonstrate an increased incidence of childhood cancer. The incidence of childhood leukemia in the subset of ~3,300 Japanese survivors exposed *in utero* at the time of the bombing did not increase significantly.[9] Only one leukemia-related death occurred in this subset of the Life Span Study during the first 15 years after prenatal radiation exposure, when the leukemia incidence peaked in radiation-exposed adults.[268] These results are inconsistent with the findings of the Oxford Survey of Childhood Cancers Study that suggested prenatal X-ray exposure was associated with an increased incidence of childhood cancer.[269] Interpretation of the Oxford Survey remains controversial because all childhood solid tumors increased at the same rate (i.e., ~40%), suggesting possible methodological problems (e.g., selection and recall biases). A 14-year follow-up study of the 1,630 members of the cohort of Japanese survivors exposed *in utero* detected two cases of childhood cancer.[270] Although this follow-up study suggested the cohort may have an increased risk of developing cancer during adulthood, the number of tumors detected was small (10 cases) and the tumor mix contained some cancers not typically associated with radiation exposure. During the first 42 years of follow-up, no cases of leukemia or breast cancer developed in the high-dose portion of this cohort; however, increase in the excess relative risk of solid cancers was dose-related, albeit with a wide confidence limit (ERR/Gy = 2.1, 90% CI: 0.2–6.0).[268] In a study of 8,000 offspring of female workers at the Mayak Nuclear Facility in Ozyorsk, Russia, 3,226 (40%) were exposed to *in utero* radiation with an estimated mean uterine γ-radiation dose of 54.5 mGy.[271] The risks of mortality from solid cancers and leukemia in this cohort born from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

1948–1988 were not statistically significant. For solid cancer mortality, the RR was 0.94 (95% CI: 0.58–1.49; ERR/Gy = −0.10; $n = 28$), whereas the RR for leukemia mortality was 1.65 (95% CI: 0.52–5.27; ERR/Gy = −0.8; $n = 6$). Updating the cohort through 2009 did not significantly alter the risk estimates or conclusions regarding solid cancer[272] and leukemia mortality.[273]

Reproductive Abnormalities

The risk of adverse heritable health effects in children conceived after their parents received radiation is very small compared with the baseline prevalence of genetic disease in humans. There is no convincing evidence that preconception exposure to environmental sources of radiation produces increased risks for congenital malformations, stillbirths, spontaneous abortions, neonatal mortality, or altered sex ratios; case-control studies for *in utero* exposure are inconsistent.[207]

Somatic Abnormalities

In all animal species, ionizing radiation produces breakage and rearrangement of the chromosomes of all diploid somatic and haploid germ cells (gametocytes, sperm, ova, embryonic cells, and stem cells). Human studies on the genetic effects of radiation indicate humans are less sensitive to radiation than mice.[9] These studies suggest the amount of radiation necessary to double the natural incidence of a genetic or somatic anomaly (i.e., the doubling dose) is ~1.56 Sv; this doubling dose is ~4 times greater in mice than humans.[274] The genetic effects of radiation are expressed as mutations in the offspring induced by parental irradiation. Potential adverse outcomes of these mutations in the offspring include: 1) serious complications of pregnancy (stillbirth, perinatal death, major congenital defects), 2) premature death, 3) induction of proteins with structural or conformational changes, and 4) sex chromosome aneuploidy. Studies of these endpoints for offspring exposed *in utero* in Hiroshima and Nagasaki suggest a positive correlation with radiation exposure; however, the differences between exposed and nonexposed persons were not statistically significant.[274] Dose-related increases in radiation-induced chromosomal aberrations (e.g., translocations, fragments, dicentrics) persisted for at least 20 years in some of the peripheral lymphocytes and bone marrow of Japanese atomic bomb survivors.[275] No clinically significant effects (mental retardation, microcephaly, leukemia) have been associated with these chromosomal aberrations.[276,277]

In Utero Exposure

Potential adverse outcomes from *in utero* radiation exposure include fetal or neonatal death, malformations, growth retardation, functional impairment, and cancer. The development of these abnormalities depends on the radiation dose received by the fetus, the stage of fetal maturation at the time of exposure, and other less well-defined modifying factors.[278] Several sources provide information concerning the effects of prenatal radiation exposure including studies of atomic bomb survivors in Hiroshima and Nagasaki,[279] pregnant women exposed to fallout from nuclear weapons testing near the Marshall Islands, and women exposed to diagnostic and therapeutic irradiation during pregnancy.[280]

Although studies of pregnant patients exposed to medical radiation suggest the human fetus is radiosensitive, animal studies do not support high radiosensitivity of animal fetuses. A study of atomic bomb survivors 40 years after *in utero* radiation exposure indicates the fetus was not more radiosensitive than adults; the frequency of translocation frequencies in blood lymphocytes did not increase with dose, except for a small, statistically significant increase (i.e., <1%) at radiation doses <0.1 Sv.[281] Additionally, rodent studies suggest cells with chromosome aberrations do not persist because fetal stem cells are less radiosensitive and their progeny replace the preexisting cell population during postnatal growth.[282]

Follow-up of 77,000 pregnant women in Nagasaki and Hiroshima did not detect a significant increase in adverse pregnancy outcomes (congenital malformations, stillbirths, perinatal deaths) within 1 week of birth; however, the data was not sufficient to exclude a small effect.[283] In the F_1 cohort of individuals born to Japanese parents exposed to radiation, there was no increased frequency of cytogenetic numerical or structural abnormalities compared with children born to unexposed Japanese mothers.[284] Other molecular studies of this cohort have not demonstrated discernible effects of parental radiation.[285] Additionally, studies of these cohorts have not demonstrated an increased prevalence of multifactorial diseases (e.g., diabetes, hypertension, ischemic heart disease) in the offspring of parents with radiation exposure.[286]

Occupational studies provide little information on fetal risks, except for a study of 3,000 offspring of radium dial painters; the deposition of radionuclides in the mother's skeleton exposed their children to radon progeny.[277] Fractionated radiation doses reduce the severity and incidence of congenital abnormalities compared with the same dose delivered in a single exposure.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Embryotoxicity

Although trauma and nutritional status confound embryotoxicity data from Hiroshima and Nagasaki, examination of this data indicates substantial fetal loss following exposure to high radiation doses. Among 30 pregnant women exposed to radiation within 2,000 m of the hypocenter, which was sufficient to produce acute radiation sickness, fetal death occurred in 7 pregnancies (23%), 6 offspring (20%) died in the neonatal period or early infancy, 5 progenies (17%) developed congenital defects, and 12 offspring (40%) were normal.[287] Comparative data on expected pregnancies revealed a reduction in the expected number of fetuses exposed to radiation at <4 weeks of gestational age.[288] Live births from mothers exposed to radiation before the 15th day of gestation did not display any congenital abnormalities.[289] These data suggest high radiation doses cause fetal demise rather than birth defects. In general, the spontaneous risks of pregnancy are two orders of magnitude greater than the extrapolated risks associated with diagnostic radiation. Data on the effects of low radiation levels on fetal demise are limited, in part because of the high rates of spontaneous miscarriage compared with the small risks of miscarriage associated with these radiation levels. Doses of low-LET ionizing radiation below 0.1 Gy probably do not increase the incidence of fetal demise.[290]

Congenital Malformations

Major anatomical malformations occur in animal species after irradiation during the period of organogenesis, including abnormalities of the central nervous system, eyes, skeleton, and, to a lesser extent, the viscera, extremities, and other organs.[291] However, these data suggest a threshold may exist for major malformations.[292] Radiation exposure does not produce unique congenital malformations. Although genetic effects appear in every species experimentally exposed to radiation, human epidemiology studies have not unequivocally linked existing radiation exposure with congenital abnormalities. Because of the causal link between central nervous system damage and *in utero* radiation exposure during the atomic bombing, case-control studies focus on the development of central nervous system malformations. In a case-control study of 672 congenital malformations near the Hanford nuclear facility, 2 defects (tracheoesophageal fistula, congenital dislocation of the hip) were statistically associated with employment at the Hanford facility.[293] Available data do not suggest a significant risk of congenital malformations following *in utero* exposure to current limits for pregnant or potentially pregnant workers.[294,295]

Postnatal Abnormalities

Data from Japanese atomic bomb survivors document a reduction in live births in the subset of fetuses exposed to radiation at <4 weeks of gestational age.[277] Analysis of these births indicates excess cases primarily of small head size and mental retardation (−21 to −29 IQ points) following radiation exposure at 4–17 weeks and 8–15 weeks, respectively. In Hiroshima, the thresholds for small head size and excess mental retardation were 0.10–0.19 Gy and 0.2-0.4 Gy, respectively.

Seizures Examination of the data from the cohort of Japanese children exposed to radiation *in utero* demonstrated an increased incidence of seizures for those members of the cohort exposed after the seventh week of gestation. The incidence of nonfebrile seizures was related linearly to *in utero* doses of >0.1 Gy.[296] When the 22 cases of severe mental retardation were eliminated from the analysis, the increase in seizures unrelated to fever was only suggestive of a statistically significant increase. Hence, the association between unprovoked seizures and cases without overt evidence of brain damage remains unproved.

Intelligence Mental retardation with microcephaly was the most frequent congenital abnormality detected in the children of Japanese mothers exposed to radiation doses exceeding 0.5–1 Gy in Hiroshima and Nagasaki and mothers exposed to pelvic irradiation during the vulnerable period of organogenesis. Seven of eleven children from Japanese mothers exposed within 1200 m of the atomic bombs developed microcephaly with mental retardation.[297] No mental retardation occurred in 194 children exposed *in utero* at a distance greater than 1200 m from the hypocenter.

The maximum time of vulnerability to the development of mental retardation (i.e., five times greater risk) occurs during the 8–15th week following fertilization (10–17th week after the first missed menstrual period).[298] A small excess of mental retardation cases occurred after exposure during the 16–25th week following fertilization. Exposure to radiation earlier than the 8th week or after the 25th week did not increase the incidence of mental retardation.[299] Irradiation of a gravid uterus at 6 months of gestation with 7.5 Gy of X-ray therapy and 1.34 Gy of cervical irradiation with radium did not produce any detectable physical or mental abnormalities in the male offspring.[300] The period between the 8−15th week

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

after fertilization corresponds to the time when the cortical neurons proliferate and then migrate from areas near the ventricles to the cortex.[301] The risk of mental retardation is ~40–43%/Gy during the 8–15th week, whereas the risk is ~four times less during the 16–25th week.[298] Epidemiology data are too limited to define the dose-response curve or determine the presence of a threshold. Significant increases in the incidence of mental retardation occur after doses exceeding 0.5 Gy; the data do not exclude a threshold of 0.2–0.4 Gy.[9]

A reduction in intelligence and school performance occurred in the cohort of 1,600 Japanese children exposed *in utero*.[9] This decrease in intellectual function was detected primarily during the 8–15th week post-conception. The effects of these factors were less for Japanese children exposed *in utero* during the 16–25th week with negligible effects from exposure during the other gestational periods. The data on intelligence scores fit a linear model with a reduction in scores ranging from 21–29 IQ points/Gy.

Microcephaly Permanent reduction in the size of the head (i.e., >2 standard deviations below the mean) with normal intelligence occurred three times more commonly than microcephaly with severe mental retardation.[288] The most vulnerable period occurs from the 6–11th week after fertilization up to the 18th week. The minimal radiation dose associated with a significant increase in risk of microcephaly was 0.1–0.19 Gy; at doses of 0.19 Gy, 11.1% of the exposed children had microcephaly compared with 4.1% of controls. At doses of radiation above 1.5 Gy, 38.5% of the exposed children had microcephaly, mostly with severe mental retardation.[302]

Parental Exposure

Little epidemiological evidence provides a causal association between preconception paternal radiation exposure and childhood leukemia or other cancers.[303] In a case-control study of 672 congenital malformations near the Hanford nuclear facility, the risk of congenital malformations in children born to parents employed at the Hanford nuclear facility was elevated, but the association was not statistically significant and unrelated to parental radiation exposure.[293] Although the number of cases was small, data on neural tube defects demonstrated a statistically significant relationship to parental preconception radiation exposure. The increased rate of neural tube defects was not explained by paternal radiation exposure or exposure to radioactive waste from the plant.[304] The odds ratio of neural tube defects ranged from 0.8–4 in children of men exposed to 0.1 Sv.

Males

The radiosensitivity of the testes germ cells depends on maturation, with type A spermatogonia being the most sensitive; later stages of spermiogenesis are highly resistant to radiation.[176,305] Although plasma testosterone concentrations remain normal after irradiation with doses of 0.1 Gy, plasma concentrations of follicle-stimulating hormone begin decreasing; oligospermia develops after radiation doses exceed 0.15 Gy. Because mature spermatogonia are relatively resistant to radiation doses of <3 Gy, the sperm count remains normal for 45 days after acute exposure; then, azoospermia occurs ~10 weeks after radiation doses of >1 Gy. Libido and potency are usually unimpaired because Leydig cells are relatively resistant to radiation-induced damage. Recovery from sterility following radiation doses of 2–4 Gy may require several years; case reports document the birth of normal offspring after extended periods of apparent radiation-induced sterility.[306] Radiation doses of >3–6 Gy are associated with permanent sterility.[121,307] Figure 39.7 demonstrates the dose-related reduction in the sperm count following single high-dose X-ray exposure to the testes.

Females

In contrast to males, ovarian irradiation is associated with decreased production of hormones and a reduction in the release of ovum. Females are born with a full complement of maturing ova that do not undergo further cell division; the ovary contains follicles at various stages of development. Based on animal studies, altered fertility including temporary sterility results from depletion of the radiosensitive mature and intermediate follicles. The period of sterility begins after single radiation doses of 1.5–6 Gy and fractionated doses of 1.5–12 Gy. Fertility returns after the maturation of the more radioresistant, immature follicles. Permanent sterility can occur after single radiation doses of 2–3.2 Gy[308] or fractionated doses of 20 Gy over 5–6 weeks.[307] The threshold for permanent sterility decreases with increasing age.[309] Disruption of the hypothalamic-pituitary-ovarian axis is a potential complication of cranial irradiation that can cause amenorrhea and infertility. In a study of endocrine function in 10 postpubertal, premenopausal women followed for a mean of 7 years after receiving cranial radiotherapy for brain tumors, 7 women developed oligomenorrhea, and 5 women had low serum estradiol concentrations.[310] Five women also had hyperprolactinemia. The mean total fractionated radiation doses delivered to the hypothalamus and pituitary were 53.6 Gy, with a range of 39.6–70.2 Gy.

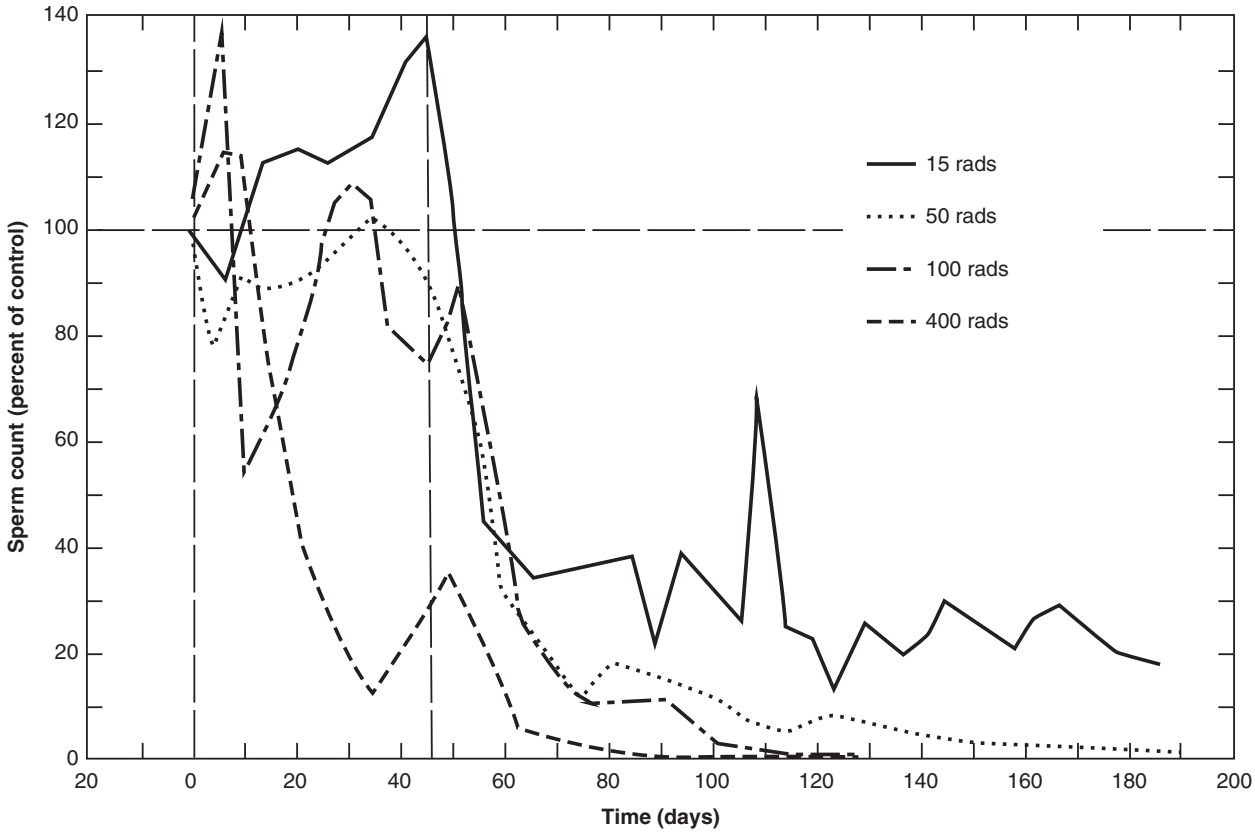

FIGURE 39.7. Dose-related reduction in sperm counts of normal men irradiated with a single high-intensity X-ray (maximum kilovolt during exposure, 190 kVp) ranging from 15–400 rads (0.15–4 Gy). (Lushbaugh).[307]

DOSIMETRY

Analytical Methods

Instruments are necessary to detect the presence of ionizing radiation because human senses do not recognize ionizing radiation. Radiation detection instruments typically detect either α-particles, radionuclides, or some combination of β-particles, γ-rays, and/or X-rays. Detection of the extremely short range of α-particles requires delicate instrumentation with thin windows to allow the passage of the α-particle to the detector. In most areas outside the defense industry, the use of instruments with β- and γ-detection capabilities is sufficient. Most portable instruments are either gas detectors that use a gas chamber as the detection media or scintillation detectors that are solid-state detectors. The two general categories of radiation sensing devices are: 1) contamination and radiation exposure survey instruments and 2) dosimetry devices. The former instruments typically measure radiation exposure rates (i.e., contamination). Contamination survey instruments measure the presence of radioactive material in counts per minute (CPM) or exposure rates rather than the cumulative radiation dose from dosimetry devices.

Incident managers and responders deploy radiation monitoring equipment depending on availability, training of responders, size and type of incident, and activities of the responders. Table 39.16 displays the usefulness of common devices for the detection of radioactive contamination, depending on the specific needs or mission.[311] No single device measures all types of radiation (e.g., α/β particles, γ-rays, X-rays, photons, neutrons); consequently, no single device is useful in all situations. These devices provide a variety of data including radiation energy (keV, MeV), exposure to γ-rays and X-rays (roentgen or milliroentgen/hour), accumulated radiation dose (Gy or rad), current dose rate (Gy/hour, rad/hour), and counts/minute or second.

Survey Instruments

Contamination survey meters (e.g., Geiger-Müeller counter) display environmental radiation in real time.

TABLE 39.16. Mission-oriented detector uses. In routine radiation emergency responses, the hot zone is the area bounded by 0.01 R (roentgen)/hour line. The roentgen is a measure of ionizing radiation that produces one electrostatic unit of positive or negative ionic charge in one cubic centimeter of air under standard conditions. Entering this zone entails the use of appropriate personal protective equipment (PPE) while being properly monitored for radiation exposure. (Adapted from REMM).[311]

Abbreviations: ● Useful = the device was designed or intended for this application without modification. ○ Marginal = the device provides useful data in the noted application with modifications to the normal mode of operation. The data should be interpreted cautiously because use of the device may create a potentially unsafe condition for the user. – Not Useful = Although the device detects nuclear radiation, technical performance characteristics limit the usefulness of the collected data. Use of the device may create grossly unsafe conditions for the user.
[a] Includes nuclear medicine diagnostics and γ-imaging cameras; [b] Current systems do not provide retrospective dosimetry as the calculation assumes the exposure occurs after the device begins measurements; [c] Includes facilities, personnel, vehicles, and material.

These devices measure and locate the presence of radioactive materials (i.e., contamination) on personnel or equipment in counts per minute (CPM) within specific boundaries, assess the extent and magnitude of a contaminated area, verify the boundaries of the hot and cold zones, and evaluate the effectiveness of decontamination measures. These devices detect only a percentage of the total energy released by radioactive material, as radioactive decays or disintegrations per minute (DPM). Consequently, DPM as measured in becquerels or curies is always greater than the CPM. An efficiency factor converts CPM to DPM, as determined

TABLE 39.17. Conversion table for converting SI units (sieverts) to traditional units (rem).

SI Units (sieverts)	Traditional Units (rem)
1 microsievert (μSv)	0.1 millirem (mrem)
10 microsievert	1 millirem
1 millisievert (mSv)	100 millirem
10 millisievert	1 rem
1 sievert (Sv)	100 rem

by Equation 39.1.

$$\text{DPM} = \text{CPM} \div \text{efficiency factor}$$
$$(\%\ \text{of total energy measured by device}) \quad \text{(Equation 39.1)}$$

The sensitivity of these instruments requires the determination of background radiation levels in the cold zone. Using this type of instrument on samples obtained by rubbing the area with moderate pressure (smear, wipe/swipe test) allows the determination of removable contamination. Moist wipes remove an estimated 20–30% of removable contamination compared with ~10% for a dry wipe. During routine surveys, the radioactivity is quantified in a 300–400 cm^2 area using a S-shaped pattern and analyzed by high-efficiency laboratory equipment, including liquid scintillation counters for α-, β-, and auger electron emitting radionuclides (^{3}H, ^{14}C, ^{32}P, ^{33}P, ^{35}S, ^{36}Cl, ^{51}Cr, ^{86}Rb, ^{125}I), auto-γ-counters for γ-emitters (^{51}Cr, ^{57}Co, ^{125}I), or gas-flow proportional counters for α- or β-emitters (^{14}C, ^{32}P, ^{33}P, ^{35}S, ^{45}Ca).

In contrast to contamination survey instruments, *radiation exposure survey meters* locate and measure radiation at incident scenes in biological equivalents (e.g., mrem or mSv/hour). The usefulness of this type of survey instrument includes: 1) locating the radiation source, 2) assessing the integrity of the object, 3) establishing the boundaries of control zones, and 4) controlling personnel exposure. Most radiation exposure survey instruments have rotating or movable β-shields that allow the detection of β- and γ-radiation in milliroentgen/hour (mR/hour) or roentgen/hour (R/hour) recorded in the biological equivalent of mrem/hour or rem/hour. Table 39.17 provides the conversion values for changing biological equivalents from SI units (sieverts) to traditional units (rem).

Radiation exposure survey equipment are not typically as sensitive as contamination survey instruments due to limitations on the type of radiation detected. Uses for the radiation exposure survey instruments include location of radiation sources, establishment of control zone boundaries, and evaluation of radiation exposure in personnel. Pancake-style detectors (CPM) are preferred for contamination surveys, whereas radiation exposure surveys typically use side window GM or "hotdog" style detectors (mR/hour). Radioisotope identifiers are radiation exposure survey instruments that identify and quantitate γ-emitting isotopes; many of these instruments also have neutron detection capability. These instruments help identify illicit sources of radioactive material by separating the illicit sources from naturally occurring radioactive materials (e.g., bananas, cat litter, ceramics, fertilizers). Traditional analog instruments often use a range multiplier switch that changes the display in multiples of 10. Personal radiation detectors are pocket-sized devices that alert the user to the presence of elevated radiation levels; however, most of these instruments are not dosimetry devices able to measure cumulative radiation doses.

Geiger–Müeller Meter

Geiger counters detect localized areas of contamination and identify sources of small amounts of radiation.[312] The detector is an argon- or helium-filled, cylindrical tube with a long, 900-V, positive, central wire connected via a meter to the walls of the tube. The detectors usually have a window at the end or side of the detector to allow the entrance of α- or β-particles. Depending on the window thickness, the Geiger survey meter can detect X-rays, γ-rays, α-particles, or β-particles. Additionally, these instruments can detect radioactive materials (e.g., ^{14}C, ^{45}Ca, ^{60}Co, ^{51}Cr, ^{137}Cs, ^{32}P, ^{22}Na, ^{35}S); however, these meters are relatively insensitive to α-particles and low-energy β-particles including detecting small amounts of ^{3}H, ^{63}Ni, ^{14}C, or ^{125}I. Radiation entering the tube ionizes gas molecules with electrons attracted to the positively charged wire and enters the electric circuit. The meter records the flow of electrons (i.e., ionizing events) as counts per minute. For charged particles (e.g., electrons), the counting efficiencies for particles that enter the halogen-filled counting tube are 90–100%. The Geiger survey meter is a pulse counter like the proportional counter; however, in contrast to the latter, the pulse height is relatively independent of the applied voltage and independent of the radiation energy. Consequently, these devices are highly sensitive survey instruments rather than dosimeters.

Measurement of α- and β-particles depends on the thickness of the detector tube and the ability of these particles to penetrate the detector wall and ionize gas molecules. For high radiation levels, an ionization chamber should be used initially because the output of the Geiger counter becomes nonlinear at high radiation doses. At very high radiation levels, the Geiger counter becomes unresponsive and fails to register any radiation. Prior to each use of the Geiger counter, the batteries

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

should be tested in the "BAT" or "BATT" position and the X1 position with a small radioactive "check" source. Typically, the halogen tubes of the Geiger counters last 6 months to 2 years. Following radiation accidents, the patient must be removed from the radiation field because the Geiger counter cannot distinguish between contamination and an external source of radiation. The end of the Geiger counter should be covered with clear plastic or a surgical glove to prevent contamination of the tip of the counter.

Ion Chamber Meter

These meters measure current flow from ion pairs produced in the detector tube, primarily from γ- and X-rays expressed in mR or R/hour. Ion pairs form during interaction of the ionizing radiation with gas molecules in the chamber; the electrons are attracted to the anode forming an electric current proportional to the amount of energy deposited in the chamber. These meters are particularly useful for measuring the high radiation levels during the operation of nuclear reactors, accelerators, X-ray machines, and radiotherapy instruments. The optimum operation of the ion chamber and the counting efficiency depend on proper air pressure in the chamber and the use of voltage sufficient to collect all free electrons (i.e., saturation current). These instruments measure excess radiation above background levels, but not specifically particle contamination.

Gas-Flow Proportional Counter

For a proportional counter, the voltage between the anode and chamber wall, the magnitude of the output pulse from the chamber, and the total energy absorbed in the sensitive volume are proportional. Consequently, this type of meter can separate α- and β-radiation because the output depends on the type of radiation and voltage. Proportional counters are simple pulse counting devices rather than instruments capable of measuring radiation exposure (e.g., ion chamber). Liquid scintillation detectors are more sensitive instruments to detect removable contamination than proportional counters.

Scintillation Detectors

The absorption of ionizing radiation and its conversion to light is the process called scintillation. The variety of scintillation detectors includes noble gases (e.g., helium, xenon), inorganic crystals (e.g., GeLi, NaI-Tl), organic crystals (e.g., anthracene), and organic liquids or solids. In contrast to Geiger counters, the number of light photons produced in scintillation detectors is proportional to the absorbed energy. Liquid scintillation counting involves the assay of a radioactive sample by dissolution in a chemical solution (scintillation fluid or cocktail). These sophisticated instruments quantify radioactivity and measure removable radioactive contamination, particularly α- and β-emitters (e.g., ^{14}C, ^{45}Ca, ^{36}Cl, ^{32}P, ^{33}P, ^{22}Na, ^{35}S) and some γ-emitters (e.g., ^{51}Cr, ^{125}I). This method offers counting efficiencies near 100% and simple sample preparation.

Personal Dosimeters

Personal dosimeters detect radiation exposure over the time the badge is worn. The dosimetry devices include self-reading dosimeters (e.g., pencil or pocket ion chamber dosimeters), electronic dosimeters with digital displays of total dose (mR, mrem), film badges, and thermoluminescent dosimeters. The latter requires off-site, specialized equipment to retrieve the exposure data. The two most common types of personnel dosimeters are the thermoluminescent dosimeter (TLD) and the film badge. Active devices provide immediate feedback on the amount of radiation or radioactivity in the environment, whereas passive devices require special, offsite processing facilities. Previously, passive electronic dosimeters using gas-filled and solid-state detectors were common personnel monitoring devices. The use of these types of monitoring devices (i.e., pencil or pocket dosimeters) is limited by the confounding influence of external factors that reduce accuracy. Active electronic dosimeters using small battery-powered instruments are more accurate than passive electronic dosimeters that require off-site reading; however, cost currently limits their use.[313]

The self-reading and electronic dosimeters allow the determination of need to leave the hot zone (i.e., >75% of full scale on low-range dosimeter scale of 0–200 mR). Self-reading dosimeters (e.g., pocket ion chambers, direct reading dosimeters, pencil dosimeters) measure the accumulated radiation dose in mR or R; typically, the dose includes only γ- and X-rays. Radiation exposure during an incident is not uniform. The dose measured by the dosimeter on the torso may not reflect the dose received by other parts of the body. When working close to radiation exposure (e.g., removing radioactive shrapnel), personal dosimeters on the finger may measure the radiation exposure more accurately than a badge on the torso.

These instruments are usually read every 15–30 minutes in highly contaminated zones. Electronic dosimeters display the same data on a digital display, typically with an audible chirping noise. Personnel dosimeters are worn either around the collar or near the waist. They provide a single measure of the radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

received by the patient at a **single** location where the dosimeter was worn; the whole-body dose depends on the direction of the beam and the extent of shielding by the body. The choice of personal dosimeters is usually a compromise between several factors including ease of handling, convenient size and shape, adaptability, clear display, resistance to deterioration, precision, accuracy, and appropriate dose range.

During a radiation accident, both pocket or pencil dosimeters and either a film badge or thermoluminescent dosimeters (TLD) typically are worn. The former two devices provide an immediate assessment of the absorbed radiation dose, whereas the latter two devices allow a slightly more accurate determination of dose after dosimeter processing. If the patient is contaminated, the film badge or TLD should be protected from contamination. Both film badges and TLDs accumulate background radiation requiring periodic replacement.

Thermoluminescent Dosimeters (TLD)

Thermoluminescence involves the release of visible light from certain heated crystals that previously stored energy from ionizing radiation. The peak light intensity is proportional to the radiation dose. Thermoluminescent dosimeters (e.g., lithium fluoride crystals) measure accumulated radiation dose; these dosimeters are typically more sensitive than film badges. Thermoluminescent dosimeters are relatively insensitive to humidity and heat. These dosimeters have replaced film badges as the most common method to monitor personnel for exposure to β- and γ-radiation. Although α-particles cannot be measured directly by TLD, their presence can be identified by their associated low-energy γ-emissions. Typical monitoring intervals are 1 month, although the exact interval depends on the history and probability of exposure to medically significant radiation levels. The major advantage of these devices is their small size and variety of forms including the ability to measure thermal neutrons with changes in the composition of lithium fluoride crystals. Ionizing radiation interacts with thermoluminescent crystals (e.g., lithium fluoride) to raise electrons from the valence band to the conduction band. Heating these crystals after exposure to radiation produces a glow or thermoluminescence. Factors to consider in the use of TLD devices include the sensitivity and range of the dosimeter, glow peak temperatures, and fading of the stored thermoluminescent signal over time. The small size of the TLD device favors its use for monitoring the exposure of extremities to radiation.

Film Badges

Photographic film is the oldest and still the most common personal dosimeter *worldwide* because of its low cost, ease of use, and simplicity. These badges typically contain photographic film that darkens with radiation exposure depending on the photon energy and radiation dose. Detection of radiation results from the interaction of the ionizing radiation with silver halide (e.g., silver bromide) grains to produce reduced silver. The amount of free silver determines the latent image on the developed film. Problems associated with the use of film badges include energy dependence, light leakage, external contamination, heat and humidity artifacts, and pressure spots on the developed film.[313] Specially designed film holders with several different filters (e.g., aluminum, cadmium, copper, lead, tin) allow the detection of β-particles along with γ- and X-ray radiation, as displayed in Figure 39.8. The use of special neutron track film allows monitoring the amount of fast neutron irradiation (0.5–10 MeV) by counting the number of proton recoil tracks; below this range the recoil protons do not form recognizable tracks. The film provides a permanent visual record of the exposure conditions during the time of use. Movement blurs the image, whereas radioactive contamination appears as blotches or hot spots.

Optically Stimulated Luminescence

Optically stimulated luminescence dosimeters are relatively new devices for measuring occupational radiation exposure by evaluating the light emitted by irradiated objects (e.g., teeth, ceramic prostheses, cellphones, and other electronic devices); this method is more sensitive (i.e., several mGy–several Gy) than film badges or thermoluminescent dosimeters. Certain crystals luminesce following exposure to ionizing radiation and stimulation with specific frequencies of laser light; the luminescence and the number of trapped electrons are proportional to the radiation dose. A laser beam scans the exposed detector material, resulting in simulation of molecules with trapped electrons that subsequently emit light

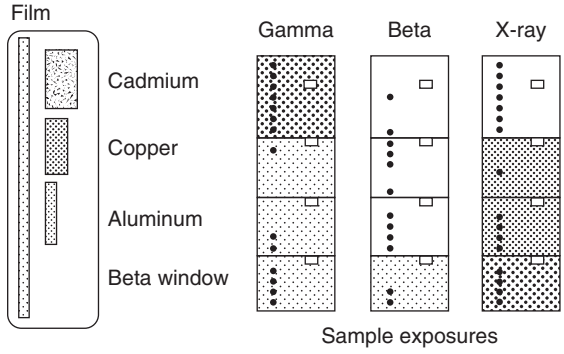

FIGURE 39.8. Composition of typical film badge with sample radiation exposures from β-particles, γ-rays, and X-rays.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with a different frequency than the laser. The radiation dose is related to the intensity of the second type of light. Like film, reading the detector does not destroy the material. Newer devices use aluminum oxide with results stored for up to 1 year after exposure. The major disadvantage is the poor stability of the signal over time.

Neutron Detectors

As uncharged particles, neutrons are difficult to detect with energies ranging six orders of magnitude (0.25–14 MeV), whereas photons range from 20 keV (X-rays)–5 MeV (γ-rays). Neutrons interact differently with different elements depending on their energies. Determination of the presence and flux of a neutron requires indirect measures based on the energy released from their interactions with matter (e.g., capture, fission, scatter). Methods to determine exposure to neutron radiation include: 1) analysis of ^{24}Na in blood, 2) estimation of ^{32}P in the hair, 3) neutron activation of metal objects (e.g., belt buckles, metal buttons, shoe nails, coins, watches, pens, hair clips, jewelry, film badge inserts), and 4) quick sort method. The physical half-life of ^{24}Na is 15 hours; therefore, the analysis of blood within the first several days postexposure is sensitive to neutron radiation doses exceeding 0.1 Gy. Hair samples help determine the amount of local neutron radiation; origin of the hair samples requires clear markings. The quick sort method involves a Geiger counter survey of the abdomen based on the number of counts per second done at least four hours postexposure.[314] The choice of detectors (boron trifluoride, proton recoil counters, fission chambers, neutron foils, neutron rem counters) depends on the energy of the neutrons involved in the sample. Track-etch detectors use the chemical etching of damage to solid foil by neutron radiation to produce visible changes using either a microscope or the unaided human eye. This type of detector (inorganic crystals, glasses) allows the determination of mixed neutron and γ-radiation because β- or γ-radiation does not produce track damage. More sensitive organic polymers are necessary to record particles with transfer energy of <4 MeV/mg/cm^2.

Accident Reconstruction

History

An accurate history helps reconstruct the radiation event and calculate the absorbed dose. This information facilitates appropriate triage of patients with serious radiation-induced injuries and improves determination of the prognosis and treatment of irradiated patients.

TABLE 39.18. Important aspects of the history of an irradiated patient.

Item	Information
Patient	Name, phone number
Company	Name product, manufacturer
Medical history	Physical injuries, treatment
External irradiation	Precise location and position in relation to source, location of shielding
Internal contamination	Route of contamination, particle size, radionuclide chemistry
Skin contamination	Location, dose rate, decontamination procedures
Rate of exposure	Time, duration of exposure
Dosimeter	Type, location on body, present location of dosimeter
Postexposure symptoms	Onset, duration of nausea, vomiting, diarrhea, anorexia
Laboratory	Timed CBC, complete metabolic panel, PT, PTT, lithium heparin tube, HLA typing
Witnesses	Names, present location, and phone number
Current radiation levels	Evaluation of potential for continued irradiation

Table 39.18 outlines aspects of the history important for the estimation of absorbed dose.

Following the detonation of a nuclear device, radiation exposure results from the high, short duration (prompt) radiation dose near the detonation device and a lower dose rate from residual radiation (fallout) with the total absorbed dose dependent on location and duration of exposure. The dangerous fallout zone where persons are at risk of ARS reaches a maximum size 1–2 hours postexplosion before shrinking in size. Sheltering in place during the first day markedly reduces the radiation exposure.[315] Most persons exposed to fallout carried downwind by atmospheric winds do not develop ARS. In general, the greater the absorbed radiation dose, the sooner the onset of postexposure vomiting occurs. Typically, the onset of vomiting begins within 1–2 hours following exposure to 2–4 Gy, whereas exposure to 4–6 Gy causes vomiting within <1 hour. However, postexposure vomiting is a nonspecific sign that does not occur in all patients exposed to these radiation doses. Hence, postexposure vomiting is a less reliable measure of radiation exposure than lymphocyte count or cytogenetic dosimetry.

Biomarkers

The assessment of chromosomal aberrations in peripheral lymphocytes is a commonly used biological

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

dosimeter for uniform, whole-body exposure; however, no single biodosimetry method provides all the data needed in a timely manner following a nuclear explosion.

Lymphocyte Count

The red marrow is highly sensitive to radiation with reduced production of granulocytes, lymphocytes, and platelets following a time- and dose-dependent course. Significant radiation exposures presenting ≥2 weeks postexposure demonstrate some evidence of lymphopenia, leukopenia, and thrombocytopenia with anemia appearing later. Figure 39.5 displays the variation of these elements with time and radiation dose. The most sensitive laboratory indicator of acute radiation poisoning is the exponential decrease in the lymphocyte count (lymphocyte depletion kinetic assay, LDK) within the first 12–48 hours after radiation exposure.[316]

The Andrew's lymphocyte depletion curve estimates the severity of radiation-induced damage based on the reduction of peripheral lymphocytes within the first 48 hours after radiation exposure, as displayed in Figure 39.6.[152] The early medical literature recommended measuring the absolute lymphocyte count as soon as possible, then every 2–3 hours to accumulate 3–4 data points for generating the LDK curve. Subsequent medical literature suggests the use of two lymphocyte counts; however, absolute lymphocyte counts vary with several factors (e.g., age, gender, race);[317] accuracy of data points on these curves increases with the number of serial blood counts. Table 39.19 displays the correlation between absorbed dose (Gy) and absolute lymphocyte count six days after acute radiation exposure.

An early fall in the lymphocyte count may occur in patients with severe burns or major trauma; therefore, a significant decrease in the absolute lymphocyte count should be interpreted cautiously, particularly in the presence of nonradiation-induced injuries. Significant decrements in the lymphocyte count may not occur following whole-body radiation exposure <1–2 Sv.

TABLE 39.19. Correlation of absolute lymphocyte count and absorbed dose (Gy) six days postexposure.

ARS Stage	Absorbed Dose (Gy)	Lymphocyte Count (10^9/L)
Preclinical	0.1–1.0	1.5–2.5
Mild	1.0–2.0	0.7–1.5
Moderate	2.0–4.0	0.5–0.8
Severe	4.0–6.0	0.3–0.5
Very severe	6.0–8.0	0.1–0.3
Lethal	>8.0	0.0–0.05

TABLE 39.20. Estimated absolute lymphocyte counts from 0–8 days after an acute radiation dose up to 8 Sv. The assumed mean baseline absolute lymphocyte count is 2.50×10^3/mL (2,500 cells/mL).

Dose (Sv)	12 Hours	24 Hours	Day 2	Day 4	Day 6	Day 8
0	2.45	2.45	2.45	2.45	2.45	2.45
1	2.30	2.16	1.90	1.48	1.15	0.89
2	2.16	1.90	1.48	0.89	0.54	0.33
3	2.03	1.68	1.15	0.54	0.25	0.12
4	1.90	1.48	0.89	0.33	0.12	0.044
5	1.79	1.31	0.69	0.20	0.06	0.020
6	1.69	1.15	0.54	0.12	0.03	0.006
8	1.48	0.89	0.33	0.044	0.006	<0.001

Table 39.20 provides a dose-dependent estimation of the absolute lymphocyte count during the first 8 days after radiation exposure ranging from 0–6 Sv. The LDK assay provides preliminary estimates of whole-body radiation doses ranging from 0.5–10 Gy up to ~8 days after radiation exposure.[318]

Granulocyte Count

The white blood cell counts may follow a predictable, dose-dependent time course with the granulocyte count increasing during the first few days after moderate radiation exposure followed by dose-dependent decline. Data from radiation accidents indicate a transient increase in the granulocyte count ("abortive rise") followed by a slow decline over the next 10–15 days. This pattern suggests a reversible hematological syndrome, whereas a rapid decline 4–6 days after radiation exposure indicates an irreversible hematological syndrome and a poorer prognosis.[319] Hematological recovery may not occur until 60–80 days after radiation exposure, particularly when partial-body shielding preserves some red marrow. The neutrophils/lymphocytes ratio is a potential adjunct to the LDK assay during early triage; however, use of this ratio requires knowledge of baseline values, particularly in burn and trauma patients.[315] The efficacy of this ratio needs further validation.

Cytogenetic Biodosimetry

The applicability of assays of cytogenetic damage in peripheral blood lymphocytes depends on the stability of the chromosomal damage. Classification of chromosomal aberrations includes unstable (dicentrics, acentric rings, and fragments) and stable (insertions, reciprocal, and nonreciprocal translocations) aberrations. Unstable aberrations usually involve loss of genomic material that contributes to underestimation of the ionizing radiation dose, whereas stable aberrations are transmissible through cell divisions and

provide estimation of the radiation dose for a much longer time than unstable aberrations.[320] Dicentric, premature chromosome condensation fragments, and micronucleus frequencies decrease with lymphocyte turnover; hence, these assays are more appropriate for recent exposures.[318] For chronic or distant radiation exposures, the assay of choice is the detection of stable translocations by fluorescence *in situ* hybridization (FISH). The two standard assays for the detection of chromosomal abnormalities are: 1) the chromosome aberration assay that recognizes chromosome breakage and rearrangement and 2) sister chromatid exchange assay. The predictive value of the latter assay for subsequent health effects is unclear; therefore, the former assay is the most common method to confirm the absorbed radiation dose. Chromatid-type aberrations usually result from chemical stress, whereas chromosome aberrations are more specific to ionizing radiation. Although ionizing radiation produces biochemical changes in the body, the lack of specificity, variable dose-effect relationship, and persistent changes limit the use of these biochemical changes as markers of the absorbed radiation dose.[321]

No one technique adequately covers all exposure scenarios (e.g., recent/homogeneous events, recent/heterogeneous events, old events, mass causality events); thus, evaluation of the absorbed radiation dose requires the integration of clinical and biological data.[322] The use of calibration curves for micronuclei and dicentrics covers similar events; however, the latter remains the most accurate and practical. Other more recently developed techniques used primarily in research include analysis of premature chromosome condensations, FISH translocations, specific fluorescent probes for protein changes (BP53, H2AX, MR11), and genetic mutation rates (glycophorin A, HLA, HPRT). The introduction of fluorescent *in situ* hybridization allows measurement of stable translocations for biodosimetry present in patients with distant (i.e., years) radiation exposures.[323] Disadvantages of cytogenetic techniques include low throughput and the expertise required to analyze the tests.

Dicentric Chromosome Assay Since the 1960s, the gold standard for biological dosimetry has been the detection of dose-dependent, radiation-specific, aberrant chromosomes with 2 cm (dicentrics) in an irradiated person's peripheral blood. A dicentric chromosome forms from the fusion of two unstable, centromere-containing fragments of a chromosome following double-stranded breaks induced by radiation directly or indirectly during aberrant repair processes. The production of dicentrics occurs almost exclusively from ionizing radiation with a relatively low frequency in the healthy population (i.e., ~1/1,000 cells). Lymphocytes and fibroblasts are the typical cells used to evaluate absorbed radiation doses; lymphocytes are usually preferred test media because of their shorter culture times and lower risk of contamination.[324] The dose-related chromosomal aberrations involve both arms of one or several chromosomes in contrast to chemicals that produce chromatid-type aberrations comprising only of one arm of the chromosomes.[325] After ionizing radiation-induced irreversible chromosomal breaks, these chromosomes rejoin in a variety of ways in a dose-related relationship. The sensitivity for this assay ranges from 0.1–5 Gy, depending on the number of metaphases analyzed with upper range limited by a nonlinear dose-response relationship caused by cell cycle arrest, depressed lymphocyte production, and cell death.[326] Radiation doses of >5 Gy impair cell proliferation resulting in fewer cells reaching metaphase and scorable cells. Ideally, the dicentric assay should be performed within a few days of radiation exposure.

The conversion of dicentrics to absorbed radiation dose involves the use of calibration curves established *in vitro* by irradiating blood samples at defined doses and dose rates. Lower limits of sensitivity in the range of 50–250 mGy require the analysis of 500–1,000 metaphases.[327] Consequently, this test is time-consuming, requiring 48 hours for the lymphocyte culture and a specialized biodosimetry staff; only two laboratories perform these tests (REAC/TS, Armed Forces Radiobiology Research Institute) with a turnaround time of ~1 week for analysis during small incidents. Thus, analysis of dicentric chromosomes helps determine the clinical outcome of radiation exposure and postincident reconstruction of the radiation dose, but its use for triage purposes is problematic. Reducing the scoring of metaphases to ≤50 significantly reduces the time requirements during large causality situations; however, this approach requires more validation because accuracy diminishes as the number of metaphases analyzed decreases.[328] Limitations to the accuracy of analyzing dicentric chromosomes include inhomogeneous radiation doses, low dose rates, and the relatively rapid elimination of lymphocytes with chromosomal aberrations.[329] Cytogenic assays assume the response of all individuals to radiation is the same; thus, this assay does not account for interindividual radiosensitivity.

Estimation of a radiation dose with cytogenic biodosimetry uses a standard 1,000 cell, 2-day count of cultured peripheral lymphocytes demonstrating chromosomes rejoined at 2 cm (dicentric) and no centromeres (acentric fragment). Prompt sampling of

TABLE 39.21. Estimation of acute whole-body radiation doses from 50-cell and 1,000 cell counts of dicentric and acentric chromosomal aberrations. The latter is substantially more time-consuming. (Adapted from REAC/TS Accident registry (https://www.osti.gov/biblio/1060542).

Dose (Sv)	Aberrations/50 Cells	Aberrations/1,000 Cells
0	0.05–0.1	1–2
1	4	88
2	12	234
3	22	439
4	35	703
5	51	1024

the peripheral lymphocytes allows the detection of external radiation doses; however, this technique is not sufficiently sensitive to detect internal doses from fallout (unless very large) or determine radiation exposure in the preceding years.[330] The accuracy of these time-dependent assays depends on the analysis of blood samples withdrawn <24–48 hours after exposure, and the analysis of blood withdrawn within this period for dicentrics helps confirm the estimated radiation dose. Table 39.21 indicates the radiation dose estimated by the number of aberrations in 50- and 1,000-cell counts.

The distribution of the lymphocytes in the peripheral circulation and the extravascular pool is a significant confounding variable for the determination of the radiation dose.[331] An average lymphocyte spends ~2 minutes in the peripheral circulation; extravascular stores of lymphocytes are 30 times greater than the peripheral circulation.[332] Because lymphocytes distribute throughout the body, rapidly delivered doses of whole-body radiation can be determined from the analysis of 500 or more metaphases for dicentric chromosome aberrations.[333] For the partial body, exposure to high doses of radiation over $^1/_3$–$^1/_2$ of the body is necessary to produce cytogenic evidence of lymphocyte damage. Following nonuniform irradiation of the body, cytogenic dosimetry helps determine the delivery of substantial radiation doses to the remainder of the body. The nonrandom distribution (overdispersion) of dicentric aberrations and the presence of large numbers of metaphases with more than three dicentric chromosome aberrations are characteristic of high radiation doses dispersed in a nonuniform manner.

Premature Chromosome Condensation Assay Interphase chromatin condenses into distinct chromosomes in mitotic Chinese hamster ovary cells or following exposure to chemical agents allowing visualization of the chromosome aberrations in lymphocytes by conventional microscopes. In contrast to the dicentric chromosome assay, progression through mitosis is unnecessary.[315] Scoring for this assay involves counting the number of premature chromosome condensation (PCC) fragments above the normal 46 chromosomes (e.g., chromosomal breaks, dicentrics, rings, translocations). Results are faster from CHO cells than from chemical methods requiring stimulation by mitogens and culturing (i.e., 2–3 hours vs. 2 days, respectively). In an *in vitro* study using blood samples irradiated with ^{60}Co γ-radiation, the PCC ring assay was linear up to whole-body doses of 20 Gy.[334] Compared with the dicentric chromosome assay, the PCC ring assay was more accurate in the high-dose range of >6 Gy and less accurate in the lower-dose range (0–6 Gy). Neither assay identified partial-body exposures. The PCC assay also allows accurate discrimination between total- and partial-body exposures to low- and high-LET radiation.

DNA Damage Assays Adverse radiation-induced responses include double-stranded DNA breaks, base lesions, and delayed cell cycle progression.[315] The kinetics of the appearance and elimination of these changes complicate the use of these biomarkers for triage and prognosis. Micronuclei are unstable chromosome aberrations that form from the failure of chromosome segments to separate during mitosis and pass into the daughter nuclei. These unstable, extranuclear chromosome fragments have a half-life of ~1 year with reliable estimate of radiation exposure up to 6–12 months after exposure. The typical whole-body dose range for this assay is 0.3–5 Gy[315] and up to 6 Gy with modification for triage; the micronuclei assay is not sensitive to partial-body radiation exposure.[335] Culturing of the cells requires 72 hours with results within 1 week of exposure if the blood is drawn immediately. Scoring typically involves 1,000 binuclear cells with accuracy decreasing with smaller sample size. Scoring requires less skill than dicentric assays; however, micronuclei are not unique to radiation exposure.[336]

During the DNA repair process, phosphorylation of the H2AX protein occurs near double-stranded DNA breaks. The peak amount of phosphorylated H2AX protein occurs ~30 minutes after radiation exposure followed by a rapid decline to baseline concentrations in a few days. The need to draw blood immediately after exposure limits the usefulness of the γ-H2AX foci assay; however, results are available within 4–6 hours for microscopy (dose range, 0.5–5 Gy) and 2 hours for flow cytometry (dose range, 0.5–10 Gy).[322]

Fluorescence *In Situ* Hybridization (FISH)
Single-color FISH (sFISH) detects interexchanges (e.g., dicentrics, translocations), whereas multicolor FISH

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

assesses induced translocations in different labeled chromosomes and whole genome analysis (M-FISH). Translocation frequencies in circulating lymphocytes persist for years, allowing analysis of radiation exposures in the distant past; however, background frequencies vary with age and individuals. Consequently, the lower limit of detection is ~0.5 Gy.[337] The detection of partial-body exposures also decreases with time as the translocation often are unstable. Accurate assessment of individual doses requires ~1,000 genome equivalent cells.[318]

Tooth Enamel by ESR

Electron paramagnetic resonance (EPR) is a nondestructive spectroscopic technique used to detect and/or identify paramagnetic systems (i.e., atoms, molecules, molecular ions) characterized by the presence of at least one unpaired electron. Placing a paramagnetic system in a magnetic field produces an energy split (Zeeman splitting), resulting in two low-lying Zeeman levels corresponding to the ground state. Spectroscopy is a sensitive measure of energy created by the production of radicals. For teeth, the main paramagnetic material involves carbon dioxide radicals with results estimating the cumulative ionizing radiation dose to the head above 0.5 Gy during the last several years to a few decades; EPR does not correlate well when the radiation exposure does not include the head.[338] Ionizing radiation produces carbon dioxide radicals from carbonate impurities in the main tooth enamel components (hydroxyl apatite). Using EPR techniques to measure the intensity of the radiation-induced signals, the absorbed radiation dose in the enamel correlates to the EPR values.[339,340] The sensitivity of EPR (i.e., ≤100 mGy) is below the sensitivity achievable with cytogenetic dose reconstruction techniques.[341] Depending on the photon energy spectrum and geometry of the radiation exposure scenario, the absorbed radiation dose in the enamel can be converted to air kerma using appropriate conversion factors. EPR techniques allow detection of natural background radiation, ^{133}Xe in fission products from the accidental release of noble gases, and ^{41}Ar in noble gases routinely released from nuclear facilities. ^{133}Xe emits β- (100 keV), γ- (81 keV), and X-ray (2 keV) radiation during decay, whereas ^{41}Ar emits β- (1,300 keV) and γ- (460 keV) radiation during decay. In a study of nuclear workers living near the Mayak nuclear facilities at Lake Irtyash in the Southern Urals, Russia, during peak releases of noble gases (i.e., 1950s), the average excess absorbed radiation dose above natural background radiation (0.7 ± 0.3 mGy) was 36 ± 29 mGy based on EPR of their tooth enamel.[342]

Optically stimulated luminescence (OSL) is an alternative technique for determining the radiation from teeth; the main advantage of this method is the use of simpler, more mobile equipment because spectral deconvolution needed for electron paramagnetic resonance (EPR)-based techniques is unnecessary for OSL. Use of OSL for acute triage is complicated by the substantial decrease in the signal from the teeth that remain in the mouth during the first 12 hours; consequently, the sample should be processed within the first 24 hours after radiation exposure.[343]

Sperm Counts

The sperm count is a sensitive biological indicator of radiation exposure based on human studies, including testicular biopsies obtained at various intervals after intratesticular tritiated thymidine injections.[344] Rapidly dividing, differentiating spermatogonia are substantially more sensitive to radiation than later-stage germ cells, resulting in a progressive loss of more mature differentiating cells (i.e., dose-related maturation depletion) following radiation exposure based on 67 men receiving a single radiation dose of 8–600 rads to the testes.[345] Depending on the radiation dose to the testes, dramatic declines in ejaculated sperm counts occur ~10 weeks after exposure, whereas azoospermia develops ~18 weeks after exposure, depending on the number of differentiating spermatogonia surviving and epididymal sperm storage. Higher radiation doses cause a more rapid onset of oligospermia or azoospermia by a direct reduction in cells in the later stages of sperm production (e.g., spermatids). Recovery of sperm production depends on the regeneration of spermatogonial stem cells and their ability to differentiate. In the latter study, the beginning of histological recovery (↑ germinal cells) ranged from 6 months for 20 rads to 7.5 months for 600 rads, whereas ↑ ejaculated sperms began at 6 months for 20 rads and 24 months for 600 rads. The initiation of sperm count recovery is dose-dependent following single, acute radiation doses with the recovery usually beginning ~7 months after exposure following a 1-Gy dose and full recovery requiring 2 years, whereas recovery begins 2 years after a 6-Gy dose and >5 years, if at all, to preirradiation levels.[344,346] Fractionation of the radiation dose (e.g., radiotherapy) reduces these timelines of recovery.[308]

Figure 39.7 demonstrates the dose-related changes occurring in sperm counts over time. Failure of the sperm count to decrease 45 days after radiation exposure suggests the testes were not exposed to radiation doses of >0.15 Gy, whereas temporary azoospermia suggests a testicular radiation dose of >0.3 Gy.[345] Characteristic changes in the blood associated with normal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

spermatogenesis during the first 2 months postexposure suggest a partial-body exposure. The absence of changes in the blood and the presence of oligospermia or azoospermia indicates exposure of the lower extremity to radiation doses exceeding 0.15 Gy. After the 18th day postexposure, the presence of epilation helps confirm the distribution of radiation in areas receiving more than 3 Gy.[347]

Dose Assessment

The amount and distribution of the absorbed dose are the most important determinants of subsequent health effects; therefore, this information has important prognostic value. Proper assessment of the absorbed dose requires an evaluation of the position and orientation of the patient relative to the source of radiation, the duration of exposure, and the characteristics (quality, strength) of the radiation.[348]

Dosimetry

Most of the absorbed dose usually occurs next to the radiation source, even though the duration of exposure is short. Information on personal and cytogenetic dosimetry confirms the reconstructed model. The presence of individuals or material between the radiation source and the patient is important primarily for low-energy radiation sources (e.g., neutrons, β-particles or low-energy γ-rays, X-rays). Personal dosimeters measure the radiation received only in one unique location; consequently, the values obtained by these dosimeters do not necessarily reflect radiation exposure to other parts of the body, depending on the radiation distribution at the time of the accident. Estimation of the radiation exposure should include adjustment for the accuracy of the dosimeter.[349] Other methods of radiation dosimetry involve biological dosimetry and theoretical calculations based on an analysis of radiation-induced changes in biological tissue (e.g., teeth, bone, blood). Serial measurements of lymphocyte counts are a particularly effective method of biological dosimetry.

Modeling

Depending on the reliability of the data, computer modeling of radiation exposure helps delineate the actual dose. The two most common methods are the Monte Carlo technique and the discrete ordinates method. Both methods require validation by dosimetry data and physical modeling.[345] Incidental alterations of the tissue (dental enamel, blood, hair) of the patient or personal belongings (film, coins, rings)[350] provide opportunistic dosimeters for the neutron spectrum and the radiation distribution.[351] Alteration of electron structure in some crystalline materials is detectable by measuring thermoluminescent signals.[352] Electron spin resonance can determine the number of free radicals produced during exposure to a radiation source and retained in specific tissues (e.g., bone, tooth enamel). The magnitude of the exposure is directly proportional to the signal from the electron spin resonance.[353]

Phantoms

Reconstruction of the accident from a single radiation source involves loading a phantom with thermoluminescent dosimeters by a health physicist to approximate the accident, particularly if the distance between the source and the patient is known and exceeds 2 m. The use of a phantom containing a skeleton and equivalent soft tissue density helps estimate the absorbed dose, especially when the accident involved several people or steep radiation gradients. Thermoluminescent dosimeters are placed in the phantom; direct calculations of the absorbed dose are recorded when the source of exposure is reactivated. Comparison of absorbed doses involves the use of the midline-tissue or whole-body doses. For most accidents involving γ-radiation, the absorbed dose in air or skin must be multiplied by 0.66 to obtain the midline tissue dose.[354]

The dosimetric data are superimposed on a CT scan of the affected portion of the body. The situation when the patient walks toward the source of radiation is more complex. Because of the inverse square law, exposure at great distances is considered a unidirectional, whole-body exposure. The rest of the exposure is calculated by estimating the radiation distribution and exposure time. Time-motion studies, interviews with the patient, and reviews of videotapes and emergency radio broadcast logs help define the sequence of events.

Abnormalities

Radiation-induced damage to specific organs results in the release of biomarkers including serum α-amylase from pancreatic or salivary gland injury and lactate dehydrogenase from hemolysis and tissue injury; however, the presence of these biomarkers is not unique to radiation-induced injuries. For patients hospitalized after radiation exposure at Chernobyl, the α-amylase level correlated to the severity of clinical manifestations of the acute radiation syndrome;[63] however, serum amylase is a very general estimate of radiation dose with very significant variability in normal values. The

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

increase in serum creatine kinase also correlated with the amount of damaged skin and the severity of the β-radiation-induced dermatitis. Bone marrow biopsy is an important measure of the radiation dose and distribution, prognosis, and treatment of the patient. Magnetic resonance imaging (MRI) is an alternative method of evaluating bone marrow recovery based on the difference in intensity of the T_1-weighted images between fat and active hematopoietic elements; however, the time and expense involved with MRI limit the usefulness of this imaging procedure in nuclear incidents.[355] Rodent studies suggest high-resolution magic angle spinning (MAS) ^{1}H NMR provides detailed information about biochemical changes in the bone marrow through *ex vivo* analysis of chemical extracts of marrow including decreased total choline content, increased fatty acids in the bone marrow, and decreased creatine content caused by radiation-induced damage to metabolic pathways in the bone marrow.[356]

Certain baseline tests may help detect the onset of late complications from radiation exposure, depending on the irradiated areas. Examples include slit lamp examination of the cornea and lens, pulmonary function tests including lung volumes for the detection of fibrosis, and bone scans for activity in the bone marrow. Abnormalities in the bone scan typically appear 4–19 months postexposure.

HEALTH SURVEILLANCE

Every reasonable effort should be made to minimize exposure to ionizing radiation as far below the regulatory dose limits as practical given economic, societal, and other relevant needs. The synonym for this approach is as low as reasonably achievable (ALARA). Reduction of the external dose of radiation involves minimizing the time near the radiation source, maximizing the distance from the source (e.g., the dose decreases with the square of the distance from the source), using available shielding, and minimizing the quantity of radioactive material handled. Methods to reduce the internal dose of radiation include control of contamination, use of proper protective clothing, elimination of food, drink, and smoking in areas of contamination, and monitoring of personnel in contaminated areas.

Risk Assessment

Chronic Low-Level Radiation

Most epidemiology data supporting an association between radiation and cancer result from acute exposure to high doses of radiation above 0.2–0.5 Gy; therefore, risk estimates of radiation exposure must be extrapolated from relative high doses to the more continuous, lower radiation levels present in medical, occupational, or environmental settings. Significant uncertainties remain in estimating radiation risks and disease probability in the low-dose region (<0.2 Gy) from disparities in the accuracy of modeling assumptions (e.g., dose assessment, low-dose/low-dose rates, relative biological effectiveness factors) and the validity of extrapolating data from radiation-exposed individuals to a healthy population.[357] Cancer is a common disease that will affect 42/100 individuals in their lifetime. Following brief radiation exposure of 100 mSv, epidemiological studies have had difficulty detecting the predicted single excess cancer case in the lifetime of 100 exposed individuals (i.e., relative risk 1.001–1.04 for low-dose radiation 1–100 mSv).[96] Variability in risk estimates at lower radiation levels occurs because of inconsistent data, assumptions about the characteristics of the dose-response curve, uncertainties about the degree of exposure, use of cancer incidence vs. cancer mortality, and several modifying factors including differences in the dose rates and individual sensitivity (e.g., age, sex, genetic susceptibility, nutritional status). Although there is considerable evidence of teratogenic effects and limited data on *in utero* carcinogenic effects of high radiation doses, there is little direct evidence to support the causal association between intrauterine exposure and subsequent heritable genetic abnormalities.

Based on current risk estimates, epidemiological studies of persons exposed to low radiation levels help determine the upper risk limits and the potential for underestimating true risks; however, chances of detecting statistically significant increases in risk are low given the small number of expected cases at low radiation levels and the presence of confounding factors and bias.[358] For survivors of the atomic bombs in Hiroshima and Nagasaki, the lowest dose interval associated with an increased leukemia incidence was 0.2–0.49 Gy; therefore, the Japanese data do not elucidate the shape of the dose-response curve below this level. Studies that produced estimates of cancer risk following exposure to external ionizing radiation primarily involved medical treatment, nuclear releases, and occupational exposures. In general, the relative risks per unit dose are greater for Japanese atomic bomb survivors than comparable subsets of medically exposed individuals.[174] Although several factors may account for the difference in risk estimates, including the higher baseline cancer risks in radiation studies of patients than in Japanese atomic bomb survivors, cell sterilization probably accounts for most of the

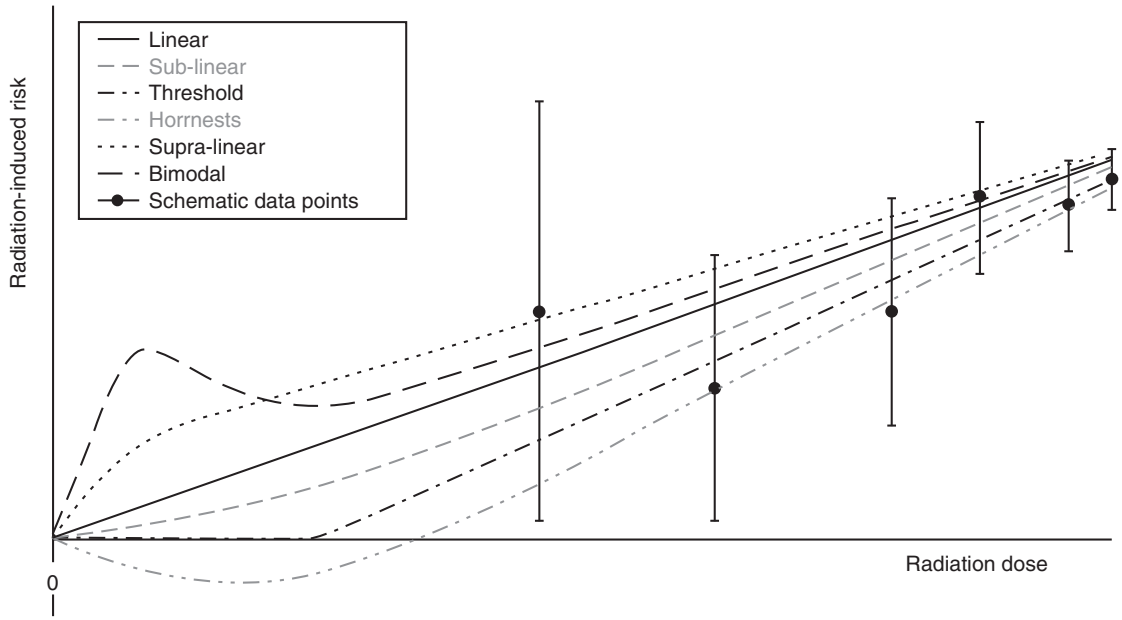

FIGURE 39.9. Several dose-response curves describe radiation-induced risks for stochastic health effects including linear, sublinear, threshold, supralinear, hormesis, and bimodal curves. The schematic data points on the graph are consistent with all the curves. For radiological protection, most organizations chose the linear curve. (Adapted from Wakeford).[254]

discrepancy between these two populations. Figure 39.9 schematically displays several dose-response curves that potentially fit low-dose exposure data. For radiological protection, most organizations chose the linear model.

Modeling

Because of data limitations, the determination of risks from cancer or genetic harm following exposure to low radiation doses (<0.1 Gy) present in environmental or occupational settings requires the use of mathematical models to extrapolate risk from high radiation doses observed following the detonation of atomic bombs and use of high-dose medical irradiation. The three most common models (i.e., linear, linear-quadratic, quadratic) adequately fit the data for exposure to radiation doses of >1 Gy; however, these models differ in the estimation of risk at lower radiation doses as displayed in Figure 39.10.

Dose-Response Curves

Quantitative animal data on dose-response relationships indicate the relationship between cancer and low-LET radiation is complex with tumor types primarily demonstrating linear or linear–quadratic relationships; a few studies suggest a low-dose threshold (e.g., thymic lymphoma, ovarian cancer) for tumors dependent on cell killing.[207] The linear model is the simplest and most conservative model for fitting epidemiological data to develop the dose-response curve for estimating radiation risk, particularly at high-LET radiation doses. Most risk estimates involving low-LET radiation (i.e., <0.1 Gy) by radiation protection organizations including the National Research Council's Committee on the Biological Effects of Ionizing Radiations (BEIR V,[9] BEIR VII[207]) use the linear no-threshold model for radiation-induced solid tumors and the linear-quadratic model for leukemia, bone cancer, and nonmelanoma skin cancers.[207] These models of radiation-induced cancer risks in the range of 0–0.1 Gy are based on mechanistic data with the risk estimate of an effect at low radiation doses usually lower for linear-quadratic than linear models.

Data from lifetime studies of A-bomb survivors are currently nearing completion as the number of survivors of the atomic bombing dwindles; therefore, models are necessary to extrapolate the future incidence of cancer based on data from cohorts followed for limited time. The dose-response relationships for individual tumor types differ in the Life Span Study of the atomic bomb survivors. For leukemia, the dose-response is curvilinear with statistically significant risk at doses exceeding 0.2 Gy, whereas nonmelanoma skin cancer risk is curvilinear with statistically significant excess risk above 0.5 Gy.[360] Most leukemia-related mortality in this

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 39.10. (a) Schematic representation of dose-response curves for three models (linear, linear-quadratic, quadratic) demonstrating the extrapolation of high-dose data for excess incidence to low-dose exposures. (b) Comparison of linear model with threshold to linear-quadratic model without threshold showing hypothetical difference between the two models at high- and low-dose exposures. Modeling of leukemia risk commonly uses the linear-quadratic function, whereas modeling of solid cancer risk usually uses the linear function. Estimating risk in the low-dose range involves extrapolation of data from higher levels. (Adapted from Richardson).[359]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cohort occurred in the first 15 years after the atomic bomb explosion, with the risk of leukemia-related deaths decreasing to negligible levels after 50 years of follow-up.[361]

Although the actual shape of the dose-response curve for current environmental radiation levels depends on model type, the widespread prevalence of cancer requires additional assumptions about the effect of radiation on the spontaneous incidence of cancer, particularly the effect of age at exposure on cancer incidence and mortality. Children under the age of 10 years appear more susceptible to the induction of cancer than adults, especially leukemia and solid tumors of the breast, thyroid, and bone.[362]

Two main types of assumptions (excess absolute risk, excess relative risk) affect the age-related changes in the risk estimates for the dose-response curves of cancer incidence and mortality following low-dose LET radiation exposure. Excessive relative risk (ERR, Equation 39.2) expresses risk as a dimensionless function of the relative risk in the unexposed population, whereas excessive absolute risk (EAR, attributable risk, Equation 39.3) is independent of the baseline risk in the unexposed group expressed as excess cases or deaths/person-year. Figure 39.11 displays the difference in risk between the additive (absolute) risk model using excessive absolute risk (EAR) commonly applied to leukemia risk and the multiplicative (relative) risk model using excessive relative risk (ERR) commonly applied to solid cancers.

$$\text{ERR} = (\text{disease rate exposed population} / \text{disease rate unexposed population}) - 1 \quad \text{(Equation 39.2)}$$

$$\text{EAR} = \text{disease rate in exposed population} - \text{disease rate in unexposed population} \quad \text{(Equation 39.3)}$$

Although mechanistic considerations suggest the relative risk model more accurately predicts cancer risks from the atomic bomb data, mechanistic and epidemiological data are insufficient to determine the appropriate model. For cancer sites other than breast, lung, and thyroid, the BEIR VII committee recommends a weighed mean combining 70% of the excess relative risk (i.e., ERR) and 30% of the excess absolute risk (i.e., EAR).[207] Risk data on the US Caucasian population are sufficient for breast and thyroid cancers to directly estimate risks, whereas this ratio is reversed for lung cancer because of the high rate of smoking in Japan and the additive effects of smoking and radiation.[363]

Modifying Factors and Excess Risk

For purposes of protection, most governmental agencies use the linear no-threshold model to extrapolate the cancer risk from high-dose exposure data to the lower doses present in environmental and occupational settings. Although epidemiological data suggest the incidence of thyroid cancer, leukemia, and breast cancer best fits the linear no-threshold risk model,[359,364] experimental evidence suggests low-dose (<10 mSv) and low dose-rate (<100 mSv/day) radiation are less effective than single, high radiation doses in inducing cancer. Because of the effectiveness of cellular repair process at low and fractionated low-LET radiation doses, the linear extrapolation of animal data usually involves correction factors including the dose and dose-rate effectiveness factors (DREF, DDREF). The dose rate effectiveness factor (DREF) measures the difference between a single large acute radiation exposure and the same dose and type of radiation following a chronic radiation exposure fractionated over time. DDREF assumes the risk of a solid cancer at low acute doses or low dose rates of low-LET radiation differs from the risk at higher acute doses seen in the Japanese atomic bomb survivors. The risk reduction for these two factors (dose and dose-rate effectiveness factor, DDREF) is usually considered equal. For cultured somatic cells, the DDREF typically ranges 2–4-fold.[365]

Based on evidence from experimental data, the International Commission on Radiological Protection (ICRP),[366] Public Health England (formally, National Radiological Protection Board), the US Environmental Protection Agency, and UNSCEAR recommend reducing linear estimates derived from Japanese A-bomb survivors and other high-dose rate cohorts by a dose and dose-rate reduction factor (DDREF) of 2.0. BEIR V estimates did not reduce cancer risk estimates by a DDREF factor, whereas BEIR VII estimates on low-dose radiation used a linear model with a DDREF of 1.5 for solid cancer risk estimates. Leukemia risk estimates fit a linear-quadratic model rather than the linear no-threshold model reduced by the DDREF factor. This factor assumes the linear component of the dose-response does not depend on dose rate; however, some authors suggest some radiobiological animal data do not support this concept.[367]

Absolute Risk The absolute or additive risk model assumes the annual increased cancer risk appears after a latent period; then, the increased cancer rate remains constant. Consequently, the excess rate is constant and independent of the background cancer rate. The additive model is most applicable when radiation acts

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

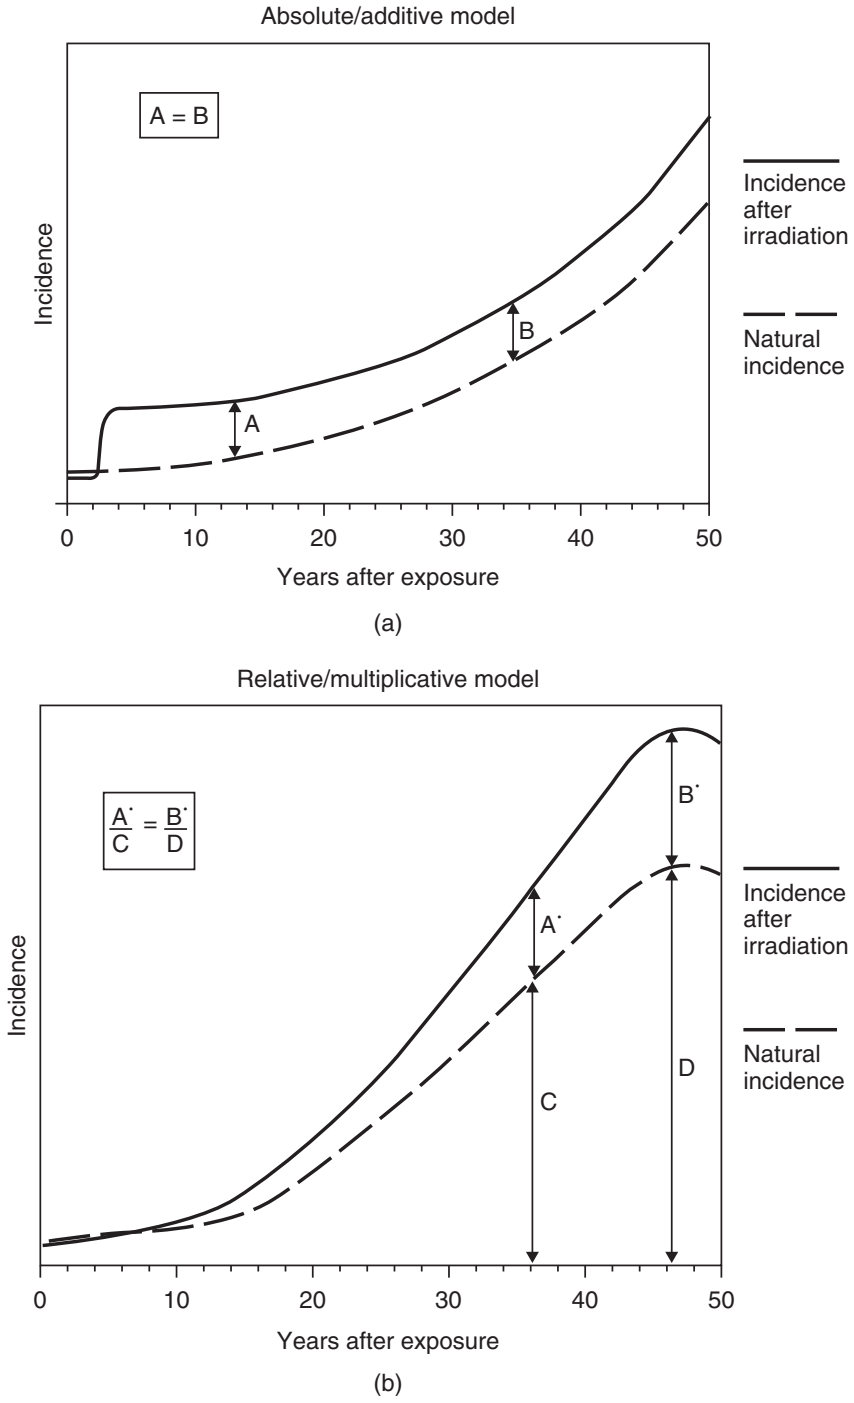

FIGURE 39.11. Schematic representation of the differences in incidence using the absolute (additive) model (a) and the relative (multiplicative) model (b). For the absolute model, the incidence increases with age after exposure with the natural incidence plus the radiation effect. The latter is constant with the radiation effect at 13 years after exposure (A) the same as at 35 years after exposure (B). For the relative model (b), the radiation effect increases with the natural incidence rate. The radiation effect at age 36 years (A′) is smaller than at age 46 years (B′) because the natural incidence is smaller at 36 years (C) than at 46 years (D). (Adapted from Richardson).[359]

independently as one of many cancer-modifying factors after initiation (i.e., tumor promoter). The excess absolute risk (EAR) refers to the difference in the rate of disease occurrence between an exposed and unexposed population; absolute risk is expressed as the excess number of cancer cases per unit of population per unit of time per unit of absorbed dose. Although the lifetime absolute risk depends on the age at radiation exposure, the annual absolute risk does not depend on the age at observation once the latent period passes; this risk does not rely on the underlying cancer rate. Leukemia, bone cancer, and nonmelanoma skin cancers follow an absolute risk model. Most models now predict very few subsequent radiation-associated leukemia deaths among atomic bomb survivors.

Relative Risk Relative risk is the ratio of the occurrence rate in the exposed and nonexposed populations with the excess relative risk (ERR) equal to the relative risk minus 1; the ERR is a measure of the effect strength. The relative or multiplicative risk model assumes increased cancer risk follows the same pattern as the natural cancer incidence with the excess cancer rate increasing in direct proportion to the baseline cancer rate. This model implies that the cancer risk after the latent period depends on age and the spontaneous cancer incidence in the population studied. This model also suggests radiation initiates the first transformation steps in the multistage theory of cancer for solid tumors with other promotional steps necessary for tumor development.[29] All radiation, host biological sensitivity, and environmental factors affect the cancer risk equally, as would occur in the early stages of the multistage process of cancer (i.e., initiation). Both the EAR and ERR vary with factors other than radiation dose, including age at exposure, attained age (e.g., time after exposure), sex, and lifestyle (e.g., smoking). The radiation-induced excess risk of solid cancers follows a time-constant relative risk model (i.e., after a latent period, the excess cancer incident is proportional to the underlying cancer incidence rate in the nonirradiated population). The relative risk model implies radiation-induced cancer will increase as the natural incidence of cancer does with the excess relative risk diminishing as the age at exposure increases, particularly following exposure at a young age.

Although current epidemiology data indicate the relative risk model fits better than the absolute risk model, some modification of the relative risk model may be appropriate for diminishing risks.[207] Extrapolating risk data from Japanese atomic bomb survivors to other populations using the relative risk model requires modification when baseline cancer rates in the two population differ. Although the baseline cancer rate for solid tumors is similar in the United States and Japan, site-specific cancer rates are not similar; the baseline rate of stomach and liver cancer is relatively high in Japan, whereas breast, colon, lung, and prostate cancer rates are relatively high in the United States. Although the relative risk model predicts higher estimates of the cancer incidence following exposure to low-LET radiation than the absolute risk model, these cancers appear later in life; therefore, the loss of life expectancy is proportionally less.[368]

Figure 39.11 demonstrates schematically the differences in incidence between the two risk models. In the absolute risk model (a), the effect of radiation on the disease incidence remains constant to the natural incidence as the age after exposure increases (A = B). In the relative risk model (b), the effect of radiation on incidence increases as the age after exposure and the natural (spontaneous) incidence increase; however, the ratio of the radiation effect/natural incidence remains constant (A′/C′ = B′/D′). The BEIR V report does not use the dose rate effectiveness factor (DREF) to reduce risks at low levels of low-LET radiation.

Leukemia and some solid tumors (e.g., breast, thyroid, bone, lung) are clearly associated with excessive radiation exposure at doses of >0.1 Gy. The dose-response relationship between radiation exposure and breast cancer incidence was linear down to 0.5 Sv; data suggest this relationship may extend to lower radiation levels.[369] For most solid tumors, studies from atomic bomb survivors indicate the relative risk model best fits published data (i.e., persons irradiated at an older age have a greater cancer risk compared with persons irradiated at a younger age). The incidence of breast cancer and lung cancer in this population does not correlate well to the absolute risk model; the latter risk appears intermediate between the two models.

Validation of Models

As seen in Figure 39.10, the linear no-threshold model provides the most conservative risk estimates at low dose levels. Each of these models approximates the true dose-response relationship at low radiation doses; however, each model has limitations. Assumptions used in these models contain large safety factors to prevent underestimation of risk for regulatory purposes; therefore, these estimations do not necessarily imply a specific effect at a given dose. Technical difficulties (e.g., large number of subjects necessary to detect small increases in the incidence of cancer at low doses) prevent experimental validation of these models. Meta-analyses of various cohorts exposed to radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

provide alternative analytical methods to determine the effect of radiation on large populations; however, these methods are limited by the bias of publishing positive rather than negative results.[370] Despite the plausibility of low-dose radiation effects, the existence of conclusive evidence of biological harm in humans at radiation doses of <10–100 mGy remains controversial.

The validity of extrapolating high- to low-dose radiation is limited by the inverse square law; to preserve statistical significance and power, this law requires the sample size to increase by the inverse square as the additional risk becomes smaller. At an exposure of 0.1 Gy, a sample size of at least 100,000 workers and a similar group of age- and sex-matched controls are necessary to detect the difference in the cancer incidence.[371] Reducing the exposure to 0.01 Gy requires a sample size of 10 million to maintain statistical power. For low-LET radiation, the dose-response curve appears concave upward with a maximum peak that subsequently declines in response to increasing dose. This latter decline reflects the killing of radiation-initiated cells that eventually would produce tumors.

Interpretation of Risk

Interpretation of the significance of risk estimates and importance of these risks to specific populations is subjective. Table 39.22 lists several factors influencing the perception of acceptable risk.

Comparisons of estimated risks with known risks help explain the significance of the estimated risks. Almost 1 in 4 annual US deaths (i.e., ~600,000) result from cancer excluding basal cell carcinomas, squamous cell skin cancer, and *in situ* carcinomas except urinary bladder. Newly diagnosed cancer accounts for ~2¾-fold more persons (i.e., ~1,700,000).[373] If the lifetime risk of dying from cancer after an exposure to 0.01 Gy is 0.1% and the lifetime risk of cancer is 20%, then the total probability of dying from cancer increases by 0.5–20.1%. Another approach compares everyday hazards with estimated risks. Assuming the annual risk of a fatal accident in the United States is 6×10^{-4}, the risk of dying from a fatal accident over 40 years is 2% ($40\times6\times10^{-4}$) or the same risk as developing a fatal cancer after exposure to a radiation dose of 1 Gy.[372] The risk of developing a fatal cancer changes over time with more effective medical treatments. Estimates of the approximate annual risk of a fatal accident include: 1) lightning, 5×10^{-7}; 2) airplane crashes, 9×10^{-6}; 3) drowning, 3×10^{-5}; and 4) motor transportation deaths, 3×10^{-4}.[359]

TABLE 39.22. Perception of acceptable risk. (Adapted from Adelstein).[372]

More Acceptable	Less Acceptable
Voluntary	Involuntary

Necessity	Luxury

Estimated Cancer Risks

Analysis of epidemiology data on radiation-induced effects on Japanese atomic bomb survivors and other medical, environmental, and occupational cohorts indicates radiation exposure causes excessive cases of leukemia and most solid cancers. At radiation doses of ≤0.1 Gy, statistical limitations complicate the evaluation of human cancer risks; hence, models are used to estimate risk in this range. For absorbed radiation doses ranging from 0.01–0.1 Gy, knowledge regarding fatal cancer risks is very limited because most epidemiological studies have insufficient power to separate small excess radiation-induced risks (i.e., <0.05/Sv) from background cancer risk factors.[374] There is no demonstrable risk of deterministic effects in this range. Linear-dose response functions fit most solid cancer data reasonably well, with the possibility of upper curve turning downward at high radiation doses. The highest risks for many cancers occur in persons exposed early in life with excess radiation-induced risks persisting throughout life, albeit at lower risk with increasing age.[375] Table 39.23 lists the estimated lifetime attributable risk of all solid cancers and leukemia incidence and mortality by the BEIR VII Committee for exposure to 0.1 Gy low-LET radiation. This model developed by the committee predicted ~1 in 100 persons would develop cancer (leukemia or solid tumors) in their lifetime following exposure to 0.1 Gy compared with 42 in 100 developing cancer in their lifetime without radiation exposure. This group primarily used Japanese atomic bomb survivor data for estimating cancer risks, except for combining data from the Japanese survivors and medically exposed persons for thyroid and breast cancers. These data do not account for the influence of smoking.

The fit for low-dose LET radiation data was closer for the linear-quadratic model than the linear model, whereas the linear-quadratic and linear models were not statistically different for all solid tumor data. The estimates for all solid tumors were reduced by a DDREF factor of 1.5 to account for the effect of low doses and

TABLE 39.23. BEIR VII Committee estimates of lifetime attributable risk of incidence and mortality for all solid cancers and leukemia per 100,000 exposed persons following exposure to 0.1 Gy. (Adapted from BEIR).[207]

Estimate (Dose)	Solid Tumors All Males	Solid Tumors All Female	Leukemia Males	Leukemia Females
Excess cases (0.1 Gy)	800	1,300	100	70
Range excess cases (0.1 Gy)	400–1,600	690–2,500	30–300	20–250
Unexposed cases (baseline)	45,500	36,900	830	590
% Cases exposed/total exposed + unexposed	1.73	3.40	10.8	10.6
Excess deaths (0.1 Gy)	410	610	70	50
Range excess deaths	200–830	300–1,200	20–220	10–190
Unexposed deaths (baseline)	22,100	17,500	710	530
% Deaths exposed/total exposed + unexposed	1.82	3.37	8.97	8.62

dose rates; the linear-quadratic model does not require that reduction. The estimated risk of cancer mortality is age-dependent, with the risk of acute exposure to radiation during childhood being approximately twice that of an adult when comparing risks of all cancers at 5 and 30 years of age. Because of the imprecision of the Japanese data, the range of estimates for excess overall cancer deaths from solid tumors ranges from 200–830 for men and 300–1,200 for women.

These estimates depend partly on certain assumptions regarding the population (i.e., male/female), age at exposure, and cancer site (i.e., spontaneous cancer rate). Table 39.24 displays the magnitude of the effect of these variables on cancer mortality following a single, acute low-LET radiation dose of 0.1 Gy in males/females. The overall risk is greater for cancer incidence than cancer mortality because some cancers (e.g., thyroid) have a good prognosis. Thyroid cancer is not included in Table 39.24 because of the low mortality associated with this cancer.

Table 39.25 lists estimated mortality risks from two different low-dose radiation exposure scenarios using the BEIR VII data. Although most governmental and industrial organizations use similar models, their risk estimates differ slightly because of different assumptions (e.g., data sets, DDREF factors, and population composition). The mortality values (excess cases/100,000 person years) for leukemia from a single, acute low-LET radiation exposure of 0.1 Gy include 50 (ICRP, 1991), 56 (US EPA, 1999), 60 (UNSCEAR, 2000), and 95 (BEIR V, 1990). The BEIR VII models predict values of 70 for women and 100 for men (the estimated risks for men

TABLE 39.24. Lifetime attributable risk of cancer **mortality** in males/females for specific cancer sites following exposure to a single dose of 0.1 Gy at various ages in years. The values are based on a linear-quadratic model for leukemia and a linear model for all other tumors. The latter model, but not the former, includes a low dose and dose rate reduction factor (DDREF) of 1.5. The values in each cell represent the number of deaths/100,000 males and females exposed to a single low-LET radiation dose of 0.1 Gy at the age (years) indicated. These values are displayed in the format male/female unless the organ occurs in only one sex. Similar tables on cancer incidence are available in the BEIR VII report. Assuming a boy had a 0.01 Gy exposure from a barium enema at age 10, his lifetime risk of colon cancer is $0.01/0.1 \times 117 \times 100{,}000$ person-years = 11.7 per 100,000 or ~1 in 8,550. Linear extrapolation can be used on all tumors except leukemia because the latter follows a linear-quadratic model (Data from BEIR VII).[207]

TABLE 39.25. Lifetime attributable risk of death from solid tumors and leukemia after scenarios (a) lifetime exposure to 1 mGy/year and (b) 10 mGy/year, ages 18–65 years. The values are based on a linear-quadratic model for leukemia and a linear model for all other tumors. The latter model, but not the former, includes a low dose and dose rate reduction factor (DDREF) of 1.5. The values in each cell represent the number of deaths/100,000 males and females exposed to a low-LET radiation dose of (a) 1 mGy/year for a lifetime and (b) 10 mGy/year from age 18–65. These values are displayed in the format male/female unless the organ exists only in one sex. Assuming a woman received 10 mGy from a CT scan annually during adulthood (18–65 years), her chances of dying from leukemia would be 220/100,000 person-years or 1 in 455. The basis of this calculation is the linear-quadratic model; therefore, simple linear extrapolations cannot be used to calculate the leukemia risk of lower doses, because the dose-response curve deviates from linearity at low doses. Similar tables on cancer incidence are available in the BEIR VII report (Adapted from BEIR VII).[207]

Cancer Type	(a) 1 mGy/year for Lifetime	(b) 10 mGy/year Age 18–65 years
Leukemia	47/38	290/220
All solid	285/459	1,410/2,169
All cancers	332/497	1,700/2,389
Stomach	13/19	66/94
Colon	53/34	273/174
Liver	14/8	72/40
Lung	99/204	492/1,002
Prostate	6.3	32
Bladder	16/21	80/108
Other	85/98	395/449
Breast, female	53	193
Uterus	3.5	18
Ovary	18	91

and women were similar in BEIR V modeling). ICRP risk estimates including a DREF of 2 are between the Japanese survivor data and the combined data of American cohorts (Hanford, Rocky Flats, Oak Ridge).[376] The United Nations Scientific Committee on the Effects of Ionizing Radiation (UNSCEAR) uses a total cancer mortality risk coefficient for the average individual in the general population of 4.5%/Gy on the absolute risk model and 7.1%/Gy on the relative risk model. No reduction factors were applied to modify the risk when extrapolating from the high-dose Japanese data; however, the UNSCEAR Committee states the reduction factor (DDREF) should range from 2–10.

Leukemia

In a meta-analysis of 10 occupational and environmental studies on radiation exposure, the estimated ERR/Gy of leukemia (excluding chronic lymphocytic leukemia) resulting from long-term exposure to a whole-body absorbed dose of 100 mGy low-LET radiation was 0.19 (95% CI: 0.07–0.32). This calculation excludes 13 studies from the original number of studies and adjusts for publication bias.[377] Five of the original studies used leukemia incidence as the endpoint rather than leukemia mortality.

Hiroshima and Nagasaki Survivors Leukemia was the first cancer associated with atomic bomb survivors, beginning a few years after exposure followed by the appearance of an increased incidence of solid tumors 10 years after the bombings.[378] Excess risks of blood cancers were observed for leukemias (i.e., acute lymphocytic leukemia, acute myelogenous leukemia, chronic myelocytic leukemia), but not chronic lymphocytic leukemia (CLL). The latter leukemia subtype has a low incidence in the Japanese population.[379] The risk of multiple myeloma and lymphomas was not clearly increased in this cohort.[380] There were 315 leukemia deaths in the Life Span Study cohort followed through 2002 with 98 (45%) excess deaths attributed to radiation exposure in the exposed survivors (>0.005 Gy).[209] The portion of excess deaths increased to ~86% at radiation doses exceeding 1 Gy. Radiation-related leukemia risk demonstrates a unique temporal pattern with higher excess deaths in the earlier years (i.e., peak ~10 years after exposure) among survivors exposed at a young age followed by a rapid decline with age. Figure 39.12 displays age-related differences in the excess leukemia deaths with the highest excess death rate occurring in young children. The dose-response relationship for leukemia demonstrated a linear-quadratic association. A small leukemia risk other than CLL remains in current survivors.[381] The estimated excess relative risk (ERR) for malignant lymphoma and multiple myeloma was not statistically significantly elevated. Table 39.23 lists the estimated lifetime attributable risk of leukemia incidence and mortality by the BEIR VII Committee for exposure to 0.1 Gy low-LET radiation.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 39.12. The estimated excess deaths from leukemia in atomic bomb survivors from Hiroshima and Nagasaki based on exposure at 10, 30, and 50 years of age (BEIRVII). [207]

The Life Span Study contains a subset of ~3,300 individuals exposed to *in utero* radiation. Only one leukemia-related death occurred in this cohort during the first 15 years after prenatal radiation exposure, when the leukemia incidence peaked in radiation-exposed adults.[268] There were only two leukemia-related deaths in this cohort studied up to age 55 years; consequently, the excess relative risk of cancer mortality from leukemia following *in utero* radiation exposure is currently not well defined in this cohort. In general, the relative cancer risks are higher for medical exposures than for Japanese atomic bomb survivors. In the Oxford Survey of Childhood Cancers case-control study of *in utero* radiation exposures from maternal diagnostic X-ray examinations, the excess relative risk coefficient for childhood cancers diagnosed before 15 years of age was ~50/Gy.[382] The excess absolute risk coefficient for incident cases was ~8%/Gy. Potential explanations for this difference include cell sterilization and higher underlying cancer incidence in the medical series.[383]

Environmental Exposure Most existing epidemiological studies of environmental radiation exposure are descriptive with ecological design using incidence, mortality, and prevalence data to estimate disease rates rather than individual measurements of radiation exposure. The former Soviet Union established the Chelyabinsk nuclear weapons production complex (PO Mayak) in the Southern Urals (Ozersk, Chelyabinsk Oblast) as part of their nuclear weapons program. The facility produced tritium, highly enriched uranium, plutonium, and plutonium warhead components. The facilities currently remain in operation. Site-specific risk estimates in the Mayak PA and Techa River cohorts have large uncertainties and highly variable unadjusted estimates that include ranges greatly exceeding the estimates detected in the Japanese cohort of atomic bomb survivors. The large variability in site-specific risk estimates primarily results from the small number of excess cases.

The Extended Techa River Cohort includes 29,873 people born before 1950 and living sometime between 1950–1960 near the Techa River downstream from the Mayak PA radioactive waste releases. In the summer of 1951, systematic measurements of radioactive contamination began in and around the Techa River with analysis of ^{90}Sr beginning in 1960 for teeth, 1976 for forehead bone, and 1974 for whole-body counting.[384] The average absorbed red bone marrow dose was estimated for each settlement ranging from 0.176–1.64 Sv.[385] The excess relative risk per gray for mortality from leukemia was 6.5 (CI 95%: 1.8–24), excluding chronic lymphocytic leukemia, with radiation exposure accounting for 63% of the leukemia-related deaths.[386]

Occupational Exposure Studies of workers in manufacturing, research, and the nuclear industry, including Mayak PA in the former Soviet Union, provide information on the risks associated with occupational radiation exposure; however, the precision of low-dose radiation exposure limits conclusions regarding risks. Although latency periods remain similar, epidemiology data from Russian workers exposed to excessive radiation at Mayak PA suggests dividing radiation doses into long-term, low doses reduces the overall cancer risk compared with single, high-dose radiation exposures. The leukemia rate in workers at this plant peaked ~2–5 years after the peak radiation exposure rates; the excess relative risk (ERR) of leukemia was ~1.4/Gy. This value is ~$^1/_3$ the risk of leukemia in Japanese atomic bomb survivors.[387,388] Epidemiological data from the Three-Country Study (the United States, Canada, the United Kingdom) and the UK National Registry of Radiation Workers provide relatively good estimates of the radiation-induced leukemia and all-cancer risks. The leukemia risk for these workers was intermediate between the linear and linear-quadratic models derived from Japanese atomic bomb survivors. The estimated risk for all cancers was smaller than the leukemia risk with the confidence interval including no risk and a doubling of the risk.

International Collaborative Study of Cancer Risk among Radiation Workers in the Nuclear Industry (15-Country Study) collected data on estimates of radiation-induced cancer risk following protracted low ionizing radiation doses for ~600,000 workers. Within

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the 15-Country Study, the cohorts of nuclear workers from France, the United Kingdom, and the United States provided most data on early workers starting in 1943. The International Nuclear Workers Study (INWORKS) is a retrospective cohort study of 308,297 workers employed for at least 1 year and followed for a mean of 27 years in the French, English, and American nuclear industries using data from the 15-Countries Study.[389] The study included 1,791 deaths from hematological cancers. The central estimate of the ERR/Sv in the French portion of the INWORKS study for leukemia excluding CLL was 3.96 (90% CI: <0–16.82; $n = 60$; $P = 0.18$) compared with 1.93 (95% CI: <0–8.47, $n = 196$) in the 15-Country Study and 1.71 (90% CI: 0.06–4.29; $n = 198$) in the UK study.[390,391] The central estimate of 15.83 for myeloid leukemia was statistically significant (90% CI: 1.53–46.12; $n = 35$; $P = 0.01$) in the French study.

Solid Tumors

Hiroshima and Nagasaki Atomic Bomb Survivors In contrast to leukemia, the temporal pattern of radiation-related risks of solid tumors gradually increases beginning several years after the bombing with approximately proportional age-related increases in the baseline cancer rates; these results are consistent with a life-long, approximately linear elevation of the natural age-specific cancer risk.[392] Follow-up studies of the atomic bomb survivors detected an excess relative risk for most solid cancers, including brain/central nervous system, colon, stomach, esophagus, liver, bladder, lung, female breast, ovary, nonmelanoma skin, and thyroid. Bladder, lung, and female breast cancers demonstrated the highest ERR (>80%/Gy) with relatively high (50–80%/Gy) risks found for the brain/central nervous system, esophagus, colon, ovary, and thyroid. The highest excess absolute risk in descending order occurred for female breast, stomach, colon, lung, liver, bladder, and thyroid cancers; these absolute risks depend on the baseline cancer rate in the Japanese population. The risks of rectum, pancreas, uterus, prostate, and kidney parenchyma cancers in irradiated and nonirradiated survivors were similar.[393,394]

Factors affecting solid cancer risk include age at exposure, attained age, and sex. In a study of 105,401 members of the Life Span Study cohort of Japanese atomic bomb survivors followed from 1958–2005, the estimated excess relative risk of thyroid cancer at 1 Gy of radiation exposure was 1.28 (95% CI: 0.59–2.70) at age 60 years after acute exposure at age 10 years using a linear dose-response model.[395] The risk sharply declined as age-at-exposure increased with little increased risk from radiation exposure at ages over 20 years. Although the magnitude of the risk decreased with age, the risk of thyroid cancer persisted for >50 years following childhood radiation exposure. The risk was greater for females than males.

The excess relative risks (ERR) of solid cancer incidence in atomic bomb survivors from the Life Span Study exposed *in utero* (2.4/Sv, 95% CI: 0.3–6.7) and survivors exposed between birth and 6 years of age (1.4/Sv, 95% CI: 0.4–3.1)[396] are similar. For all solid tumors in the Japanese survivors exposed to whole-body radiation doses of >0.005 Gy, the attributable portion related to radiation is ~11% (853/17,448 solid cancer incidence cases).[21] This attributable portion of solid cancers increases to 48% for survivors receiving at least 1 Gy. Both the ERR and the EAR estimates for solid cancers are ~50% higher for women than men. The risks of cancer are highly age dependent with the risk of developing cancer ~2 times higher for exposure at age 10 years than at age 40 years. The excess lifetime risk per Sv for solid cancers in Japanese survivors exposed at age 30 is 0.10 (male) and 0.14 (female); the values are $\sim{}^1/_3$ for survivors exposed at age 50 years.[392] The excess risk for solid tumors appears linear up to ~3 Sv. Risk estimates currently do not indicate that *in utero* radiation exposure confers a greater risk of solid tumors in adults than childhood exposure. The estimated lowest dose range with a statistically significant elevation of the ERR for all solid cancer mortality included zero (range, 0–0.20); formal dose-threshold analysis did not suggest the presence of a threshold.[393]

Environmental Exposure Ecological studies of populations residing near nuclear facilities or exposed to nuclear fallout do not typically contain individual estimates of radiation doses or risks. A follow-up study of 3,440 persons exposed as young children primarily to ^{131}I from the Hanford nuclear facility in eastern Washington State detected no increased thyroid cancer risk.[397] The estimated median dose was 97 mGy (range 0.003–2,823 mGy) with a mean of 174 mGy. The cumulative incidence of thyroid cancer did not increase with increasing dose ($P = 0.25$). A retrospective cohort study screened 3,709 Marshall Island residents born before the Castle BRAVO hydrogen-thermonuclear test on March 1, 1954.[398] Age-specific radiation doses for the Utirik atoll and ^{137}Cs deposition levels on individual atolls provided the estimated radiation dose based on the atoll of residence. Although the results suggested the prevalence of thyroid cancer increased with quartile of estimated dose, the increase was not statistically significant (adjusted OR = 1.67, 95% CI: 0.73–3.83; $P = 0.15$) when comparing the highest (weighted Utirik

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

dose = 187.2–6,766.6 mGy) and lowest (weighted Utirik dose = 0–34.1 mGy) quartiles of radiation exposure. The estimated risk coefficient of thyroid cancer following exposure to radioactive iodide in fallout on the Marshall Islands was 1.5×10^6 persons per cGy/year.[399]

In the Extended Techa River Cohort, residents in the Southern Urals exposed to radioactive waste from the Mayak PA complex, the excess relative risk per gray for mortality from solid cancers in this cohort was 0.92 (95% CI: 0.2–1.7); radiation exposure accounted for an estimated 2.5% of solid cancer-related deaths.[386] The relative risks of esophagus, lung, and stomach cancers were similar in the Techa River and Japanese atomic bomb survivor cohorts.

In cleanup workers exposed to radiation at Chernobyl, the estimated excess relative and absolute risks of thyroid cancer were 5.31 (95% CI: 0.04–10.58)/Gy and 1.15 (95% CI: 0.08–2.22) $\times 10^4$ person-years/Gy, respectively.[400] The estimated risk of excess thyroid cancers is ~40 cancers/year/Sv/100,000 persons.[401] An 8-year follow-up study of a cohort of workers at Chernobyl detected an excess absolute risk of thyroid cancer of 11.5 cases/10^5/Gy (95% CI: 0.8–22.2).[400] The estimated range of the radiation dose was 0–0.25 Gy with an uncertainty factor of 2.5–3.0. After 30 years, follow-up of 110,645 Ukrainian cleanup workers mostly with low-level radiation exposures, the standardized incidence rate was elevated for thyroid cancer (SIR = 4.18, 95% CI: 3.76–4.59) along with multiple myeloma (SIR = 1.61, 95% CI: 1.01–2.21) and female breast cancer (SIR = 1.57, 95% CI: 1.40–1.73).[402]

In a study of 309,130 residents from the most contaminated Russian territories of Bryansk, Kaluga, Oryol, and Tula oblasts affected by the Chernobyl accident during the follow-up period of 1991–2008, the excess relative risk per Gy (ERR/Gy) was statistically significant for children and adolescents ≤17 years of age at the time of the Chernobyl accident, but not for older residents.[403] The ERR/Gy was 3.22 (95% CI: 1.56–5.81). A study of ^{131}I exposure from atmospheric nuclear tests in Nevada during the 1950s analyzed thyroid cancer incidence data on 18,545 cases from 8 Surveillance, Epidemiology, and End Results (SEER) tumor registries for nearby residents from 1973–2004.[404] The estimated ERR per Gy for radiation doses received before 1 year of age was 1.8 with a 95% CI of 0.5–3.2; however, the lack of a dose-response for children exposed during ages 1–15 years suggests the presence of biases (dose estimation, case ascertainment from migration) inherent in ecological studies. Most recent epidemiological studies did not detect any substantial deviation from currently accepted risk estimates for low-dose radiation exposure, including the Japanese atomic bomb survivor cohort.[207,358]

Occupational Exposure The nominal cancer fatality rates for working populations are usually slightly lower than those for the general population because of the susceptibility of younger persons to the stochastic effects of radiation. Bias in dose estimates, confounding factors, and comparability of the populations (e.g., age at study, sex, age-at-exposure, follow-up period) complicate the precision of comparing data from workers and Japanese atomic bomb survivors.[405] Except for the Oak Ridge National Laboratory study, early studies of workers in the United States exposed to external radiation were negative; however, the confidence limits are wide; the upper limits of the combined data did not exclude risks compatible with Japanese atomic bomb survivor cohort.[406,407] The overall mortality of the Oak Ridge population was small; the median cumulative radiation dose of this cohort was only slightly above the average annual background dose (1 mSv) of external radiation in the general population. The all-cancer dose-response estimates from this cohort were an order of magnitude above current estimates; however, the number of cancer cases was small in the higher dose groups, and the increase in cancer mortality occurred primarily in those cancers related to smoking (e.g., lung cancer). Several studies of European nuclear workers suggest a positive but statistically nonsignificant relationship between cumulative radiation dose and cancer risk (all solid cancers, leukemia excluding chronic lymphocytic leukemia); these studies also report similar risk estimates. In a mortality study of 59,021 French nuclear workers with a mean cumulative radiation exposure of 22.5 mSv followed for ~25 years, the central estimate of the excess relative risk/Sv (ERR/Sv) was 0.34 (90% CI: –0.56 to 1.38; $n = 2{,}312$; $P = 0.30$) for all solid tumors.[408] In comparison, the central estimate of the ERR/Sv for all solid tumor mortality (excluding leukemia) in the 15-country European nuclear workers was 0.87 (90% CI: 0.16–1.71; $n = 4{,}770$ deaths),[409] compared with an ERR/Gy of 0.47 (90% CI: 0.18–0.79 lagged 10 years, $n = 17{,}957$ deaths) in the INWORKS study of nuclear industry workers from France, the United Kingdom, and the United States;[410] an ERR/Sv of 0.28 (90% CI: 0.02–0.56 lagged 10 years, $n = 6{,}921$ deaths) in the UK National Registry for Radiation Workers Study;[411] and an ERR/Sv of 0.14 (95% CI: −0.17 to 0.48) in 119,195 US Department of Energy nuclear workers.[412] In comparison, the excess relative rate for male Japanese survivors of the atomic bombing exposed at ages 20–60 years was 0.32/Sv (95% CI: 0.01–0.50).[390] In the cumulative dose range 0–100 mGy (mean = 17.4 mGy primarily

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from external photons), the INWORKS data on excess relative risk were similar to the Japanese data, with the excess risk persisting for several decades; however, the INWORKS data were less precise. Excluding lung cancer did not significantly alter the excess relative risk of cancer death, suggesting smoking did not confound the results. Solid cancer excess risk was restricted to radiation exposure at age 35–50 years (ERR/Gy = 0.75, 90% CI: 0.23–1.32; 10-year fixed lag), diminishing 30 years after exposure.[413] For exposure at age 50 years and older, the ERR/Gy was 0.51 (90% CI: −0.15 to 1.23).

Estimated Noncancer Risks

Although studies of Japanese survivors indicate an increased risk of some noncancer diseases, direct evidence of increased noncancer risks at low radiation doses (<0.1 Gy) is lacking.[207] Consequently, data are inadequate to determine risk in this range.

Lens

Cataracts developed in Japanese survivors receiving high radiation doses within 3–4 years after the bombing; posterior subcapsular opacities were the characteristic ocular lesion.[414] The estimated threshold for the development of these opacities was 1.5–2 Gy; cataracts that significantly obstruct vision were not present at radiation doses below 5 Gy.[366] Analysis of longitudinal data from the Adult Health Study cohort of atomic bomb survivors collected during 1958–1986 did not detect a statistically significant dose-response relationship ($P = 0.39$) between lens opacities and radiation dose.[415] However, following the cohort for an additional 12 years (1958–1998) resulted in a statistically significant positive dose-response for cataracts ($P = 0.026$); the $RR_{1\,Sv}$ was 1.06 (95% CI: 1.01–1.11).[416] The excess cataract cases/Sv/10^4 person's years was 8 with an attributable risk of 4%. Overall, the excess risk of cataracts decreased with age after exposure.

Current data suggest the threshold for cataracts is lower. Of 6,066 Japanese atomic bomb survivors, 1,028 underwent their first cataract surgery between 1986–2005.[417] The estimated threshold dose was 0.50 Gy (95% CI: 0.10–0.95 Gy) for the ERR model and 0.45 Gy (95% CI: 0.10–1.05 Gy) for the EAR model. Using the linear ERR model for a 70-year-old individual exposed to 1 Gy at age 20 years, the excess relative risk was 0.32 (95% CI: 0.17–0.52).

Thyroid Disease

A survey study of thyroid disease in 4,091 atomic bomb survivors exposed over 50 years earlier demonstrated a statistically significant ($P < 0.001$) linear dose-response relationship for the prevalence of all solid nodules, benign nodules, and cysts.[210] The incidence of thyroid diseases was identified in 44.8% of the participants ($n = 1833$), including 32.2% of the men ($n = 436$) and 51.0% of the women ($n = 1397$); the difference between exposed and unexposed controls was statistically significant ($P < 0.001$). The mean and median thyroid radiation doses were 0.449 Sv and 0.087 Sv, respectively. The authors estimated ~28% of all solid nodules, 31% of benign nodules, and 25% of cysts were attributed to radiation exposure. No statistically significant dose-response relationship was observed for positive antithyroid antibodies ($P = 0.20$), antithyroid antibody-positive hypothyroidism ($P = 0.92$), or Graves' disease ($P = 0.10$). The estimated risk coefficient of thyroid nodules following exposure to radioactive iodide in fallout on the Marshall Islands was 8.3×10^6 persons per cGy/year.[399]

Circulatory Disease

Uncertainty about lifetime risk estimates is greater for noncancer diseases than solid cancer risks. Data from the Japanese atomic bomb survivors suggest the lifetime risk of death from radiation-associated noncancer disease after childhood exposure to 1 Sv is ~$^1/_2$ the risk for solid cancer, whereas the estimated lifetime risk in individuals exposed as adults is similar for radiation-associated noncancer disease and solid cancers.[418] These data are compatible with a threshold of 0.5 Sv for radiation-induced noncancer disease. In the Life Span Study, cardiovascular disease mortality including stroke accounts for over ½ of the overall deaths. Data suggest a radiation-related dose-response for heart disease independent of smoking and other confounders. For heart disease in this cohort of 86,611 Japanese atomic bomb survivors, the estimated excess relative risk per gray was 0.14 (95% CI: 6–23%, $P < 0.001$).[419] Although a linear model best fits the data, suggesting excess risk even at lower doses, the dose-response effect over the range of 0–0.5 Gy was not statistically significant.

In the Russian cohort of 53,772 recovery operation workers (liquidators) arriving at Chernobyl within the first year after the Chernobyl accident, the mean external whole-body dose was 0.161 Gy with a range of 0.0001–1.42 Gy.[420] The average ERR/Gy for the incidence of cerebrovascular disease was 0.45 (95% CI: 0.28–0.62, $P < 0.001$) with no latent period. Data from the cohort followed from 1986–2000 indicated a statistically nonsignificant elevation of the ERR coefficient for circulatory disease incidence of 0.18 (95% CI: −0.03 to 0.39).[421] The radiation risks were not adjusted for known cardiovascular risk factors (e.g., alcohol consumption, hypercholesterolemia, obesity, smoking). Although the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risk of cerebrovascular disease morbidity increased for doses >150 mGy, the duration of radiation exposure did not significantly affect the risk.

The 15-Country Study of nuclear industry workers did not detect statistically significant or dose-related increase in mortality from noncancerous diseases (ERR/Sv = 0.24, 95% CI: −0.23 to 0.78; $P_{trend} = 0.16$) or circulatory diseases (EER/Sv = 0.09, 95% CI: −0.43 to 0.70; $P_{trend} = 0.37$).[422] The clinical significance of radiation exposure in this range on factors influencing cardiovascular mortality including atherosclerosis, hypertension, and chronic renal disease remains unclear. Although some studies suggest a positive relationship between circulatory diseases and low-level ionizing radiation, the causal relationship between circulatory disease and cumulative radiation exposure in the workplace is not well established, in part due to the lack of an agreed mechanism for radiation-induced circulatory disease at low radiation doses.

Mental Retardation

Based on the BEIR V review of Japanese atomic bomb survivor data, the risk of mental retardation for children exposed *in utero* at 8–15 weeks of gestation was a 4% chance of occurrence per 0.1 Sv.[9] The risk associated with radiation exposure during other periods of gestation appears to be less. Although the dose-response curve for the risk of developing mental retardation is not defined precisely, the BEIR V report indicated the data do not support the concept of a threshold for this effect.

Mutations

Hereditary damage and carcinogenesis are the two primary stochastic effects of ionizing radiation exposure. The risk of radiation-induced human genetic disease following exposure to low-dose radiation is very small compared with baseline risks in the general population.[207]

Although there is no clear evidence for radiation-induced germ cell mutations (birth defects, chromosome aberrations, Mendelian disorders) in humans, the lack of sensitive, economic biomarkers and few data limit conclusions regarding the presence of these changes in humans. The extrapolation of mouse data to humans suggests at least 1 Gy of low-LET radiation is necessary to double the underlying mutation rate in humans. Heritable effects have not been conclusively documented in Japanese atomic bomb survivors; however, the low mean radiation level (<0.5 Gy) and limited sample sizes restrict the power of a study to detect statistically significant increases in genetic damage in Japanese children.[9] Stable chromosomal aberrations remain in Japanese survivors over 65 years after the bombing.[284] The shape of the dose-response curve was concave upward for doses of 1.5 Gy, but the curve plateaued somewhat at higher doses.

The BEIR V report concluded more research was necessary to estimate the amount of genetic damage produced by a given radiation level, whereas the United Nations Scientific Committee on the Effects of Ionizing Radiation (UNSCEAR) estimated the genetic risk coefficient for hereditary harm to the first two generations of a population of reproductive age to be 0–1.2%/Sv of the effective dose equivalent delivered. The estimate of the risk of hereditary disease for all generations in an average population that includes persons in the nonreproductive year was 0–2%/Sv of the effective dose equivalent. The BEIR V Committee estimated the risk of a clinically severe autosomal dominant mutation at 5–20 cases/10^6 live births/0.01 Sv/generation.[9] The risk of a clinically mild autosomal dominant aberration was slightly less; the risk of X-linked and recessive mutations was <1 case/10^6 live births/0.01 Sv/generation.

Occupational/Environmental Monitoring

The primary radiation exposure for workers occurs in the nuclear power industry and the medical field with potentially high background radiation levels in uranium miners and flight personnel.[423] Occupational radiation exposure of workers in nuclear fuel cycle activities may average an annual dose of 3–8 mSv for the reactor operation. Generally accepted radiation protection principles include: 1) justification – every new practice should produce a net positive benefit, 2) optimization – all exposures should be kept As Low As Reasonably Achievable (ALARA) after considering current economic and social factors, and 3) limitations – individual radiation exposure from controllable sources should be subject to dose limits and some limitation of risk.[424] The latter typically involves limiting the radiation risk below 1 fatal cancer/1,000 person/year during the lifetime of the exposed individual. This value represents a 5% lifetime risk of fatal cancer/Sv for an annual occupational exposure limit of 20 mSv averaged over 5 years. Exceeding the dose limit is unreasonable on any basis; dose constraints may be set at a fraction of the dose limit as a boundary to optimize radiological protection from a specific source. The concept of constraints on dose and risk limits represents a shift from dose limits to radiological protection methods to ensure dose limits are not exceeded.[425] Control areas are necessary for worker protection if routine environmental monitoring cannot predict safe dose limits; supervised areas are required if radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

levels exceed public dose limits. The International Commission on Radiological Protection (ICRP), the National Council on Radiation Protection and Measurements (NCRP), and the American Conference of Governmental and Industrial Hygienists (ACGIH) have similar guidelines on occupational and environmental exposure to ionizing radiation. The National Radiological Protection Board estimates the lifetime excess risk of fatal cancer after fetal radiation exposure at $\sim 10^{-5}$/mSv. The most vulnerable period for the fetus is 8–15 weeks after conception; irradiation during this period is associated with an estimated reduction of 0.03 IQ points/mSv; however, the minimal size of the change is insignificant given doses usually present in the work environment.[426]

US Occupational Safety and Health Administration (OSHA)

The current US occupational guideline for chronic exposure to ionizing radiation is 5 rem (0.05 Sv) in a 12-month period. Table 39.26 lists the US OSHA maximum permissible dose equivalents for occupational exposure.

US Nuclear Regulatory Commission (USNRC)

The USNRC established adult occupational dose limits similar to those of the ICRP and ACGIH. The total effective dose equivalent is 50 mSv (5 rem), with the committed dose equivalent to any individual organ or tissue other than the lens of the eye being 500 mSv (50 rem). The US Nuclear Regulatory Commission (USNRC) is an independent agency of the federal government that formulates regulations on radiation exposure from nuclear energy through the US Code of Federal Regulations, whereas the National Council on Radiation Protection and Measurements (NCRP) is a congressionally chartered, nongovernmental organization that provides guidelines and disseminates information on radiation exposure. The deep-dose equivalent and the shallow-dose equivalent are the whole-body and external skin dose (whole-body or extremities), respectively, from an external ionizing radiation source. The lens dose equivalent represents the equivalent radiation dose to the lens of the eye from an external ionizing radiation source. The lens dose equivalent was 150 mSv (15 rem), while the shallow-dose equivalent to the skin of the whole body or extremity was 500 mSv (50 rem). In 2017, the NCRP reduced the recommended annual lens occupational dose limit to an absorbed dose of 50 mGy.[427] Radiation doses exceeding the annual limits are subtracted from limits for planned special exposures during the current year and lifetime. The deep-dose equivalent must be applied instead of the effective dose equivalent measured by external personal monitoring, unless the dosimetry method is an approved NRC technique.

TABLE 39.26. Maximum permissible dose equivalent for occupational exposure, OSHA https://www.osha.gov/ionizing-radiation/introduction/ionizing-attachment-six. The organization website should be consulted for any updates on the specific restrictions and recommendations.

Combined Whole-Body Exposure	Value
Prospective annual limit	50 mSv (5 rem)
Retrospective annual limit	100–150 mSv (10–15 rem) any 1 year
Long-term accumulation	[(age in years) – 18] times 50 mSv (5 rem)
Skin	150 mSv (15 rem) in any 1 year
Hands	750 mSv (75 rem) in any 1 year; (250 mSv/3 months)
Forearms	300 mSv (30 rem) in any 1 year; (100 mSv/3 months)
Fertile women (with respect to fetus)	5 mSv (0.5 rem) in gestation period
Population	1.7 mSv (0.17 rem)/year

International Commission on Radiological Protection (ICRP)

The ICRP accepts a linear dose model without a threshold for stochastic effects (i.e., cancer, heritable effects) and a dose and dose-rate effectiveness factor (DDREF) of 2 for low radiation doses and dose rates. For deterministic effects (tissue reactions), absorbed doses below 100 mGy are not associated with clinically relevant functional impairment.[428] For risks to the embryo and IQ following *in utero* exposure, the threshold is ~100 mGy, whereas the threshold is ~300 mGy for the most sensitive prenatal periods (8–15 weeks postconception). The recommended exposure limits for women with declared pregnancies and the public are similar. Table 39.27 lists the ICRP annual dose limits.

The ICRP recommends that the annual dose equivalent received by pregnant women be limited to 30% of the 5 mSv limit (i.e., 1.5 mSv) for the public; the rate of accumulation should not exceed 0.5 mSv per month. The IRCP recommends a supplementary dose limit of 2 mSv in the abdomen of a pregnant woman for the duration of the pregnancy. For women with internal exposure to radionuclides, the recommended protection limit is 1/20th the annual limit on intake. The job of a pregnant woman should not involve a significant probability

TABLE 39.27. ICRP guidelines for dose limits in planned exposure situations for adult workers. (Based on ICRP 2007).[428]

Limit	Occupational Exposure	Environmental (Public) Exposure
	Effective dose (stochastic)	
Annual	20 mSv	1 mSv
5-year average	50 mSv/year maximum not to exceed 100 mSv over 5 years	Maximum may exceed 1 mSv/year with average over 5 years not to exceed 5 mSv
	Equivalent dose (deterministic)	
Lens of eye	20 mSv per year averaged over 5 consecutive years, and 50 mSv in any single year	15 mSv/year
Skin	500 mSv/year	50 mSv/year
Hands and feet	500 mSv/year	–
Embryo/fetus		Approximately the same as public

of high, accidental radiation doses or incorporation of radionuclides.

The ICRP separates exposure situations into planned, existing, and emergency to focus attention on the control of natural and artificial radiation sources, particularly the use of dose constraints and reference levels for existing and emergency situations.[429] Emergency exposures usually result from the inability to control a planned source due to an unexpected loss. These situations require urgent and timely actions to mitigate exposure. The reference level represents the maximum residual dose or risk level to allow radiation exposure to occur; consequently, this level represents the maximum acceptable residual dose after implementation of an optimized protection strategy. For radiation protection purposes, reference levels for emergency exposure situations should be set in the band of 20–100 mSv effective dose (acute or per year), as indicated in Table 39.28.[430] In contrast, existing exposure situations do not require rapid action to ensure protection.[431]

Dose constraints limit the range of options considered during the optimization process, whereas reference levels refer to restrictions on dose or risk during existing or emergency situations that indicate the importance of optimizing protection by reducing the radiation exposure. Table 39.28 demonstrates the actions and requirements for the three bands of radiation exposure. The upper band (20–100 mSv) relates to reference levels for emergency situations, whereas the middle band refers to planned, existing, and emergency situations.

The necessity of occupational restrictions following an exposure exceeding the recommended dose limits depends on the individual situation; such an event requires a thorough examination of the design and operational aspects of the radiological protection of the involved facility.[366]

American Conference of Governmental and Industrial Hygienists (ACGIH)

The ACGIH guidelines use the effective dose in mSv (1 mSv = 0.1 rem) as the unit of radiation exposure; the effective dose is the sum of equivalent internal and external radiation doses defined by the absorbed dose for each organ multiplied by a specific weighting factor.[432] The ACGIH accepts the weighting factors defined by the ICRP.[428] Table 39.29 lists the recommended ACGIH values for occupational exposure to radiation. These guidelines exclude background radiation from cosmic, implanted, radon, and terrestrial sources. The objectives of these guidelines include: 1) preventing radiation-induced deterministic effects, 2) minimizing stochastic effects to levels comparable to fatal occupational accidents, and 3) reducing radiation doses as far below the guidelines as practicable.

TABLE 39.28. ICRP framework for reference levels and dose constraints. (Adapted from Wrixon).[429]

Effective Dose Bands (Acute or Annual)	Action for Control	Requirements	Examples
<1 mSv	Source	Periodic evaluation of exposure pathway	Public dose constraints in planned situation
1–20 mSv	Source or exposure pathway	Individual dose assessment and training in a planned situation	Reference level for household radon; dose constraints for caregivers of patients taking radiopharmaceuticals
20–100 mSv[a]	Exposure pathway	Evaluated dose reduction	Radiological emergency reference level

[a] Upper bound established for deterministic effects. The upper bound of the other two bands are the dose limits for workers and the public.

TABLE 39.29. American Conference of Governmental and Industrial Hygienists (ACGIH) guidelines for ionizing radiation exposure. (ACGIH).[432]

Exposure Type	Annual Exposure Guideline
Effective dose	
Single year	50 mSv
5-Year average	20 mSv/year
Equivalent dose	
Skin, hands, feet	500 mSv
Cumulative effective dose	10 mSv × age (years)
Embryo/fetus equivalent dose	0.5 mSv (monthly)

US Department of Homeland Security

The US Homeland Security Department and the National Security Council-led Domestic Readiness Group provide guidance for radiation exposure limits for medical workers performing emergency services, as outlined in Table 39.30.[433] Each responder should make an informed decision regarding acceptable radiation doses from their actions to save lives based on a complete discussion of risks they may experience. Medical staff at an emergency facility is unlikely to exceed these limits unless the facility is heavily contaminated, whereas emergency workers in the field may significantly exceed these levels depending on the specific circumstances (e.g., β-radiation received by Chernobyl emergency responders).

Medical Screening

Adults exposed to excessive radiation levels (e.g., residents of Belarus, southwest Russia, northern Ukraine near the Chernobyl accident) receive routine physical examinations with emphasis on detecting thyroid abnormalities. In addition to regular cancer screening and routine blood chemistry tests, thyroid function tests, complete blood cell counts, and urinalysis also are recommended.[434] The major complications of patients developing acute radiation sickness were skin atrophy, β-burn fibrosis, and cataracts.[73]

Accidental Overdose

Routine screening tests and annual physical examinations following a single, high-dose radiation exposure are probably not necessary unless a significant radiation exposure occurred including: 1) whole-body radiation of >0.25 Sv, 2) skin dose of >6 Sv, or 3) absorbed organ dose of >0.75 Sv.[176] When specific organs are involved, baseline tests (e.g., sperm counts, slit lamp examination, mammography, digital arteriography, nuclear medicine radionuclide angiogram, technetium thyroid scans) are useful. The physical examination should be directed toward establishing baseline function in the injured organs and determining changes in function (e.g., arteriolar narrowing, cataract formation, atrophy, fibrosis).

TABLE 39.30. US Department of Homeland Security and Interagency Policy Coordination Subcommittee for Preparedness and Response to Radiological and Nuclear Threat dose limit guidelines for emergency workers. (Adapted from National Security Council led Domestic Readiness Group).[433]

Total Effective Dose Equivalent Guideline	Activity	Conditions
50 mSv (5 rem)	Annual Occupational radiation exposure limit	All reasonably achievable actions to minimize radiation dose
100 mSv (10 rem)	Infrastructure protection and restoration of necessary for public welfare in low-hazard areas (light damage zone, fallout areas)[a]	Dose of >50 mSv despite all appropriate actions/controls. Monitoring and appropriate respiratory protection provided
250 mSv (25 rem)	Lifesaving, medical response, infrastructure restoration, or protection of populations in medium-hazard areas (moderate damage zones and nondangerous fallout areas)	Dose of >50 mSv despite all appropriate actions/controls. Monitoring and appropriate respiratory protection provided
>250 mSv (>25 rem)	Life-saving and critical infrastructure missions in high-hazard zones including dangerous fallout zone to protect significant population from substantial risks of injury, illness, or death	All missions are evaluated by Incident Commander including hazards, value, chances of success, and potential exposure to lethal doses. Responder is aware doses may be ≥500 mSv with risk of cancer or acute radiation syndrome.
		Dose >50 mSv despite all appropriate actions/controls. Monitoring and appropriate respiratory protection provided

[a] Excludes dangerous fallout zone and elevated radiation areas.

Occupational Exposure

Preemployment physical examinations should be given to employees potentially exposed to radiation levels exceeding 30% of the allowable dose limits. The basic and routine preemployment physical examinations are similar with emphasis on the route and type of radiation exposure. Careful attention should be given to documenting the existence of current or past diseases of the skin, ventilation, renal disease, and blood disorders because these types of diseases may affect the elimination or development of radiation-induced diseases.

The frequency of physical examinations depends primarily on the health of the worker and the extent and type of radiation exposure. Neither laboratory nor physical examinations are reliable methods to control radiation exposure. Routine screening for cancer among workers exposed to low levels of radiation is probably not beneficial. Routine screening (whole-body scanning, chest X-ray) of workers exposed to radionuclides is a standard practice. The use and frequency of whole body or organ radioactivity counts and the assessment of radionuclide excretion depend on the judgment of the physician about the potential exposure and the reliability of environmental monitoring.

TREATMENT

The most important determinants for initial treatment following accidental or malevolent radiation exposure involve: 1) number of victims and resources available, 2) occurrence of conventional and/or thermal injuries, 3) time since exposure (i.e., soon, minutes to 48 hours vs. late, days to weeks), and 4) presence of external and/or internal radioactive contamination.[153] Medical treatment is usually necessary only for individuals receiving a whole-body radiation dose exceeding 1 Gy. The classification of radiation injuries includes: 1) uncomplicated trauma without radiation exposure, 2) simple external irradiation without contamination or trauma, 3) combined radiation and traumatic injuries without contamination, 4) external contamination with or without wound contamination, 5) internal contamination, and 6) no radiation exposure or trauma. Immediately life-threatening injury from a radiation dose occurs extremely rarely with treatment typically limited to palliative therapy; therefore, initial treatment involves the stabilization of the patient by the basic tenets of acute trauma life support (airway management, adequacy of ventilation, control of hemorrhage, cervical spine immobilization) without regard for the radiation exposure level or extent of contamination. Patients irradiated by an external source (e.g., γ-rays, X-rays) are not radioactive; these patients do **NOT** represent a radiation hazard to medical personnel. Contamination occurs when radioactive gases, liquids, or solids are deposited on the skin, ingested, and/or inhaled. Except in Chernobyl where firefighters and medical personnel received serious irradiation from β-emitter contaminated water, emergency medical responders are not usually exposed to clinically significant radiation levels during resuscitation of irradiated victims. Treatment of radiation causalities is most effective when the whole-body radiation dose is between 2–6 Gy (200 and 600 rad), with radiation doses above 6–8 Gy often causing fatalities despite medical care.[435]

Initial Triage/Assessment

The primary responsibility of the initial medical team is the identification of injured victims and initiation of emergency medical care. Radiation sites (triage, treatment, transport) are determined by the event. Typically, these events would involve industrial accidents, power plant failures, or radiation dispersion devices ("dirty bombs"). The three general radiation sites include: 1) in/near blast zone (very limited responder time), 2) along plume (limited responder time), and 3) low-radiation dose zone for collection of causalities for transportation.[436] Triage begins with assessment of physical trauma and burns followed by radiation exposure and estimation of whole-body dose.[437] Most irradiated and/or contaminated victims require triage and decontamination rather than immediate medical care. Cardiopulmonary resuscitation of a contaminated victim is usually necessary only in the presence of life-threatening trauma or the exacerbation of an existing medical condition; the presence of contamination is rarely a serious threat to the rescuer. After the treatment of the life-threatening condition, the patient should be moved away from the area of contamination with backboards as necessary to protect the cervical spine. Intravenous lines should be inserted in uncontaminated areas of the skin only when necessary to treat hypotension or dysrhythmias. The presence of contamination does not interfere with the use of extrication equipment or medical equipment. Table 39.31 outlines the priorities during initial triage, assessment, and transport to the emergency department.

The goal of triage is the evaluation, medical stabilization, and categorization of the radiation incident victim to accomplish the greatest good for the most people. In contrast to blast injuries and thermal burns,

TABLE 39.31. Prioritized field operation protocol. (Adapted from Ricks).[438]

1. Approach the scene with caution, looking for hazardous substances.
2. Position the command post, personnel, and vehicles at a safe distance of 200–300 ft upwind of any suspected radiation hazard.
3. Notify proper authorities and adjacent hospitals.
4. Use protective gear, survey meters, and dosimeters as soon as possible.
5. Evaluate the presence of injured victims.
6. Determine and treat life-threatening injuries immediately without delaying advanced life support to relocated victim or assess contamination. Perform routine emergency medical procedures during extrication.
7. Remove victims from the radiation hazard area with proper transfer techniques to minimize further injuries. Relocate victims with suspected radioactive contamination to a safer area within the controlled zone.
8. Identify wounds and cover them with sterile dressings.
9. Monitor victims for contamination at the control line after medical stabilization. Remove the clothing of accident victims when radiation levels above background levels indicate the presence of radioactive contamination. Wrap contaminated clothes in marked sheets or bags.
10. Move ambulance gurney to the clean side of control line after covering the gurney with a clean sheet or blanket. Place victim on the gurney; cover and secure for transport. The victim should remain on the backboard if used.
11. Rescuers should remove protective gear at the control line before leaving the controlled area. Ideally, gloved personnel who have not entered the controlled area should transport the victim.
12. Base station contact should be initiated during transport to advise the hospital of the medical condition of the victim and determine the need for additional information or treatment.
13. The hospital radiation protocol should be followed upon arrival.
14. The radiation safety officer should evaluate and clear the ambulance, equipment, and crew before returning to regular service.
15. Personnel should refrain from oral intake including smoking during initial evaluation, treatment, transport, and emergency department interactions until released by the radiation safety officer.

radiation-induced injuries are usually not immediately life-threatening; therefore, the treatment of the former injuries takes precedence over the treatment of radiation-induced injuries. The immediate priority is medical and surgical stabilization; subsequently, patients are assessed for radiation-induced injury based on the radiation type (isotope, nuclear release), presence of internal and/or external contamination, radiation dose, and expected complications. Evaluation of the latter includes location during the incident, symptoms (e.g., time to emesis, diarrhea), blood (e.g., lymphocyte counts when available), and physical examination.[438] Point of care assessment determines treatment priorities and destination of the patient. Subsequent estimates of an individual dose involve secondary assessment with high throughput screening (e.g., absolute lymphocyte count, dicentric chromosomes) as indicated. The threshold for the acute radiation syndrome is a whole-body dose of ~0.75–1 Gy with medical management and additional screening potentially necessary for estimated whole-body exposures of 1–2 Gy, particularly for long-term complications. However, treatment delays usually do not cause immediate danger to life. Victims with estimated whole-body radiation doses exceeding 2 Gy typically need prompt treatment for the biological damage associated with acute radiation syndrome.

The goal of the emergency medical responder is the administration of basic life support, removal of the victim from areas of radiation hazard, and transportation of the patient to the appropriate emergency department. The identification of a radiation hazard at the scene may be difficult because radiation is not evident to our senses like chemicals (e.g., ammonia). Three different labels are affixed to radioactive packages depending on the rate of radiation emission including: 1) white label I – almost no radiation (maximum, 0.005 mSv/hour on surface), 2) yellow label II – low radiation level (0.5 mSv/hour at 3 ft), and 3) yellow label III – higher radiation level (2 mSv/hour at 3 ft). Regulation requires vehicles transporting yellow-III packages or radioactive packages without labels to display radioactive placards. The presence of these placards alerts emergency medical responders to use the procedures for hazardous materials and notifies the dispatcher to contact the appropriate state and local agency about potential radiation hazards. A controlled zone should be established around these radiation hazards with protective gear used by emergency personnel in this zone. Contaminated victims should remain in the control zone where their contaminated clothes can be placed in safe containers, whereas uncontaminated victims should be removed from the area with proper patient transfer techniques. Emergency personnel should remove protective gear at the control line; however, ambulance personnel should wear double gloves while attending to the victim during transport. No smoking, drinking, or eating should occur during field operations.

When radioactive contamination is suspected, protective clothing (i.e., universal precautions: boots or shoe covers, mask, cap, gown, fire turnout gear, surgical or disposable gloves) should be worn if available; however, lifesaving medical care should not be delayed

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in the absence of protective gear unless there is a clear danger to the emergency medical care providers.[439] The use of self-contained breathing apparatus depends on the presence of inhalable radioactive contamination (e.g., smoke, dust, gases). Standard guidelines for protection from microbiological contamination including surgical masks (N95 masks are preferred, if available) are usually sufficient protection for most radioactive emergencies.

Previously, the most common radiation accident involved radiation exposure from sealed sources of γ-rays and X-rays utilized in industrial radiography or nondestructive testing.[438] Although these sources are frequently small, they produce high ionizing radiation levels. These sources should be shielded from any workers by dense metal, particularly within 6–10 ft of the source. An explosion in a nuclear facility may imbed highly radioactive metallic fragments in a victim; this type of accident presents a significant hazard to emergency personnel unless properly shielded. Reducing radiation exposure by emergency medical personnel includes: 1) minimizing time in the control area to the amount necessary for the proper stabilization and transportation of the patient, 2) wearing protective clothing and standing behind shielding whenever possible, 3) working at least 3 ft (i.e., arm's length) from the contamination source whenever possible, and 4) containing the contamination within a limited area. When proper precautions are observed, radionuclides on the surface of *intact* skin rarely produce hazardous exposure levels in emergency medical personnel.[440]

Triage Categories

Categories of triaged victims based on whole-body radiation exposure include: 1) mild radiation exposure with no serious injuries (<1–2 Gy), 2) immediately life-threatening radiation exposure (2–6 Gy), and 3) grave radiation exposure (>6–10 Gy) with survival less likely, particularly >10 Gy. The Radiation Emergency Assistance Center/Training Site (REAC/TS, https://orise.orau.gov/reacts/index.html) provides prehospital and hospital medical guidance and flow charts to assist clinicians with triage and prioritization of radiation accident victims, as demonstrated in Figure 39.13. Reassessment and repeat triage are necessary features of medical responses to nuclear incidents during the movement of causalities and arrival of additional resources. Table 39.32 lists the four triage categories, triage card colors, and descriptions of the triage categories. Under normal triage conditions with conventional standards of care, estimated radiation doses of 2–10 Gy indicate the need for immediate care (red card). Causalities with radiation exposure in the 2–6 Gy range are priorities to help deliver optimal cytokine treatment when few resources are available.[437] The presence of comorbid conditions and combined injuries suggests the need for more immediate care, depending on the availability of resources.

In contrast to the more common nuclear incidents (industrial accidents, nuclear power plant failures, dirty bombs), nuclear detonations create massive casualties and severely damage infrastructure. Minimization of morbidity and deaths from nuclear detonations requires implementation of the following strategies during the first 4 days: 1) organize and deliver trauma care to patients with acute injuries, 2) screen survivors to identify risks for radiation-induced injuries and determine priorities for treatment and evacuation, 3) recognize survivors with nonfatal radiation exposure and serious radiation exposure that benefit from cytokine therapy and priority evacuation, and 4) issue "shelter-in-place" orders for at least 24 hours to minimize radiation exposure in high-fallout areas. The Exposure And Symptom Triage (EAST) tool is a simple screening method that improves initial assessment and triage when sources (e.g., serial lymphocyte depletion counts) are scarce following a nuclear detonation (https://remm.hhs.gov/EAST-toolnotes.htm).

Contamination Survey

Without interfering with medical care, victims should be monitored for the presence of contamination, particularly in wounds and on the face. The initial concern is the detection of contamination rather than the amount of contamination; victims should be separated into contaminated and uncontaminated areas. Radiation levels two to three times above background radiation levels indicate contamination. Ultimately, the objectives of the survey include the measurement of the contamination level, the radiation dose rate in the treatment area, the accumulated radiation dose as measured by dosimeters (e.g., direct reading devices, thermoluminescent, quartz fiber, finger rings, film badges), and the identity of the radioactive materials. The order of scanning and decontaminating the patient begins with open wounds, then the face and facial orifices followed by intact skin. Localized contamination areas should be outlined with a permanent marker and covered with clean gauze or available wrapping until the beginning of decontamination. All persons in the control area should be identified and assessed for the presence of contamination. All contaminated persons should be decontaminated; the

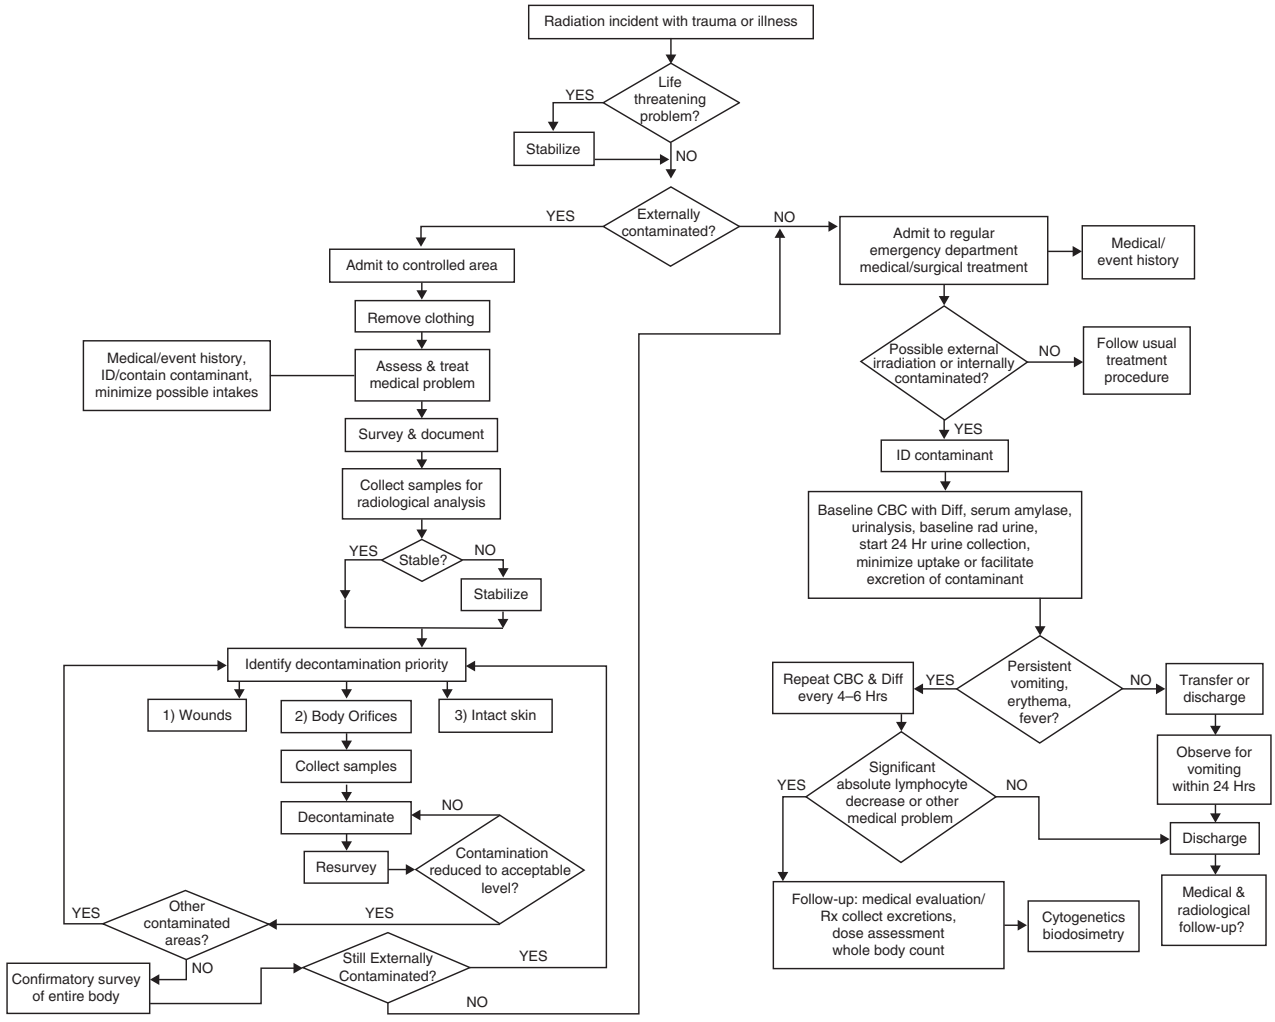

FIGURE 39.13. Radiation Emergency Assistance Center/Training Site (REAC/TS) flow diagram for prioritizing medical treatment during radiation incidents involving ionizing radiation and/or radioactive contamination.

TABLE 39.32. Triage categories for causalities from physical/burn trauma and/or radiation. (Adapted from Coleman et al.).[437]

Category (Estimated Dose)	Card Color	Description
Immediate	Red	Priority treatment group based on trauma/burn and radiation
Delayed	Yellow	Treatment is limited and safely delayed after priority group. Total body surface area burns of 10–20% indicate worsening prognosis and the need for more immediate care, especially in the elderly
Minimal A (<0.5 Gy)	Green	Minor/no physical injury or minor burns with estimated radiation dose requiring no early medical evaluation. Triage can be focused on other categories
Minimal B (0.5–2 Gy)	Green	Minor/no physical injury or minor burns with some radiation exposure. Some initial treatment (e.g., fractures) may be necessary in the initial 4-day time period. Biodosimetry and clinical reassessment (e.g., multiple initial reassessments, long-term registries) may be important in the upper ranges of this exposure range. However, treatment for acute radiation syndrome is unlikely
Expectant	Black	Symptomatic treatment only (i.e., palliative care)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

victim should be referred to the emergency department for evaluation and further decontamination regardless of the extent of obvious injuries.

Measurements of the radiation dose rate (mSv/hour) help determine the health risk to victims and responders. Typically, the dose rates to responders in the medical setting are relatively low because the amount of radioactive material is usually small. Radiation detectors may not detect very low-energy β-particles (e.g., tritium) or α-contamination, particularly when shielding (e.g., gauze, layer of blood) or distances over 3 ft separate the probe and contamination.

Initial Decontamination

Rapid decontamination of the victim decreases the amount of incorporated radionuclide while reducing long-term risks (e.g., cancer, cataracts). Radioactive contamination almost always results from radionuclides that emit high-energy α-particles, β-particles, and/or photons (γ-, X-rays). High-energy photons (γ-rays, X-rays) and neutrons penetrate the body causing internal damage; however, *direct* exposure to these radiation types does not usually produce radioactive contamination in the victim. Removal of outer clothing and shoes reduces external contamination by ~90%.[435] Subsequent decontamination of the skin and hair with soap and warm water along with gentle brushing to dislodge radioactive particles attached to skin proteins significantly reduces the remaining contamination. Contain the contamination by carefully cutting and rolling clothing away from the face and body to the bag. These bags should be sent to the laboratory for analysis in bags specially marked as radioactive material. The amount of further decontamination in the field depends on the ability of the available facilities to prevent the spread of contamination from the victim.

Special care is necessary to avoid internal contamination of the victim by spreading contamination through open wounds, nose, mouth, ears, and eyes including the use of water-proof paper rather than cloth drapes. Most contamination on intact skin functions like loose dirt; the contamination can be removed by routine washing at the appropriate facility including the emergency department. Repeated measurements of the decontaminated areas determine the effectiveness of decontamination techniques, particularly in open wounds. The presence of discomfort during the decontamination process suggests corrosive chemicals or excessive trauma from the decontamination technique rather than radioactive contamination. Medical personnel should wear protective clothing and gloves consistent with universal precautions; with appropriate precautions and adequate irrigation techniques, the radiation dose transferred to medical personnel is minimal. Decontamination of most Chernobyl workers at the accident site resulted in radiation exposures for medical personnel below 10 mGy.[118]

Transport and Hospital Notification

The patient should be transported to the emergency department as soon as the initial resuscitation and decontamination are completed. A clean stretcher covered with a sheet or blanket is placed near the control line, separating the contaminated and uncontaminated areas. Wounds should be covered with sterile dressings, and the patient should be secured to a backboard if a cervical spine injury is suspected. The patient is then placed on the clean stretcher, and the sheet securely wrapped around the patient to minimize any further spread of radioactive contamination. The extension of an arm through the sheet will allow the infusion of intravenous solutions and the measurement of vital signs; the ambulance floor should be lined with securely taped sheets or plastic. The patient should be transported by an ambulance crew that did not enter the controlled area. The emergency medical crew should change gloves and their outer clothing.

The base station should be contacted as soon as possible to prepare the radiation emergency area at the hospital. Important information to transmit from the ambulance crew to the base station includes: 1) the number and medical condition of the victims including the number of contaminated patients, 2) the extent and locations of external contamination, 3) evidence of internal contamination, 4) the identity and form of the radionuclides including all shipping papers, manifests, material safety data sheets, and labels, 5) evidence of other physical or chemical hazards, 6) the time, duration of exposure, and cause of the accident, and 7) the presence of prodromal symptoms (e.g., nausea, vomiting, weakness, fatigue, prostration, anorexia). The initial treatment of radiation-exposed patients requires no specialized facilities; after triage and stabilization, patients with high radiation doses can be transferred to specialized centers without reducing their chances of survival. Uncontaminated persons with nausea, vomiting, or diarrhea should be referred or transported to a hospital for evaluation of whole-body radiation exposure.

Emergency Department Care

Medical treatment for irradiated patients is usually necessary for victims receiving >1 Gy of whole-body

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 39.33. General objectives for treating seriously injured and contaminated victims in approximate order of importance. (Adapted from Koenig et al.).[435]

Type of Treatment
1. First aid and resuscitation
2. Medical and surgical stabilization
3. Definitive treatment of severe injuries
4. Prevention and minimization of internal contamination
5. Assessment of external contamination and subsequent decontaminationas neeeded. Decontaminated patients cause no radiation risk to medical personnel
6. Treatment of minor injuries
7. Containment of contamination to treatment area and prevention of responding personnel contamination
8. Minimization of external radiation to rescue and treatment personnel
9. Assessment of internal contamination
10. Treatment of internal contamination concurrently with other priorities, depending on urgency and time required
11. Assessment of local radiation injuries/doses
12. Patient counseling regarding expected long-term effects/risks
13. Long-term follow-up for patients with significant whole-body irradiation and/or internal contamination

radiation. Table 39.33 lists the approximate sequence of important priorities for the emergent treatment of victims exposed to serious radiation doses.

Preparation

Serious radiation incidents requiring a specialized response include nuclear reactor meltdowns, explosion of a large radiological dispersal device (dirty bomb, RDD), nuclear weapon detonations, and surreptitious placement of a radiation exposure device in a public area. Following notification of a radiation accident entailing contamination, the emergency response team should prepare the radiation emergency area (REA) for the arrival of the contaminated patient.[441] The main purpose of the REA is to limit contamination in this area by using predetermined protocols similar to strict isolation precautions. Ventilation of the REA should be stopped and the air ducts closed. All patients, uncontaminated victims, and nonessential personnel and equipment should be removed from the area. Butcher paper or brown wrapping paper secured with tape should line the REA and the ambulance path to the REA. A control line marked by rope and tape should clearly delineate the REA from noncontaminated parts of the hospital. No person or equipment should leave the REA until it is monitored for the presence of contamination. Taping saran wrap or plastic sandwich bags over handles and switches in the REA reduces the spread of contamination by hand. The treatment table should be draped with a waterproof covering (e.g., disposable surgical pack cover).

Each member of the emergency response team should be dressed in waterproof surgical clothing, double gloves with different colors, and shoe covers with all open cuffs and seams taped. Outer gloves should be changed frequently. Facial protection includes a surgical mask and eye/splash protection. A radiation dosimeter should be worn in an easily accessible place on the outside of the clothing. Documentation of the time course of clinical signs and symptoms (i.e., gastrointestinal, hematopoietic, cerebrovascular, skin) is necessary to appropriately triage the victims, select therapy, and assign a prognosis.

Arrival

Uncontaminated victims can be admitted to the normal treatment areas of the hospital. Serious medical problems in contaminated patients are a priority that should be treated before evaluation and treatment of radiation injuries. Critically ill patients should be transported immediately to the REA. Radiation-induced illness rarely causes alterations in vital signs and consciousness; therefore, patients with abnormal vital signs or mentation have concomitant injuries. If the patient is medically stable, the nuclear medicine technologist should assess the contamination level of the victim at arm's length from the patient. If the radiation level is <0.1 mGy/hour at 1 ft, personnel may work safely at arm's length from the patient. Otherwise, personnel should stay 10 ft from the contaminated patient when direct access to the patient is not necessary.[442] The treatment table or gurney should contain several layers of sheets. Pregnant healthcare workers should have the option of being exempt from the direct care of numerous contaminated patients.

The contaminated patient should be transferred to the stretcher with the decontamination tray from the ambulance and transported to the REA. Reassessment of the patency of the airway, the adequacy of ventilation, and the stability of the circulation is then necessary. A comprehensive physical examination precedes the completion of the complete survey of the victim for the location of radioactive contamination. The usual history regarding allergies, medications including recent nuclear medicine tests, occupation, accidents, past medical illness, and operations should be obtained. The patient should be specifically asked about the onset and duration of prodromal symptoms of the acute radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

syndrome (i.e., nausea, vomiting, diarrhea, anorexia, fatigue, weakness). Most contaminated debris reside on clothing and shoes. The clothing of the victim should be cut from the head toward the feet if not already done; the contaminated material should be placed in a bag marked nuclear waste near the ambulance. The clothes should be cut in the midline along the legs, arms, chest, and abdomen; then, the clothes should be carefully folded away from the skin to minimize the amount of radioactive material settling on the patient. An 8-ft security zone should be established around the ambulance to prevent the spread of contamination. All equipment and supplies used to treat the patient must remain in the ambulance. The ambulance personnel should change clothing; the ambulance and the personnel should be surveyed for contamination before returning to service.

If contamination is discovered after the patient has been admitted, the resuscitation and assessment of the patient should continue while the area surrounding the patient and attending staff is secured with control lines to prevent the spread of contamination. Personnel should remove contaminated clothing, shower, and dress in clean clothing before leaving the contaminated area. All people leaving the new control area should be surveyed for contamination. Contaminated clothing should be stored outside the Emergency Department in a secure area because of the potential radiation hazard. Any obvious dirt or debris should be discarded in an appropriate receptacle.

External Decontamination

Ideally, decontamination occurs in the field before transport to the emergency department, where removal of clothing can reduce ~90% of the contamination. Additional decontamination measures reduce residual contamination on the body, decrease incorporation of the radionuclides into the body, and prevent the spread of contamination to other people. The patient's questions regarding the procedures and use of protective clothing during the decontamination process should be answered by someone knowledgeable about radiation procedures. Before decontamination, moist swabs of body orifices should be collected along with moist or dry swabs of contaminated wounds. Nasal secretions can be obtained from paper tissue after instructing the patient to blow into the tissue. Long forceps should be used to collect debris and place the debris in lead containers. Orifices should be flushed gently with water or saline while using frequent suction to prevent the forcing of contamination further into the orifices. The patient must be instructed not to swallow. Table 39.34 outlines the methods for controlling contamination in the emergency department.

TABLE 39.34. Contamination control techniques in the emergency department.

1. Set up controlled area with sufficient size to treat the anticipated number of victims
2. Avoid tracking contaminants by covering floor areas
3. Restrict access to the controlled area and monitor everyone and everything leaving the controlled area
4. Observe strict isolation precautions including double bagging and protective clothing
5. Consider buffer zone or secondary control line for additional security
6. Control and label waste by using large, plastic-lined containers for suspected contaminated items (e.g., clothing, dressings, linens)
7. Control ventilation
8. Change drapes, instruments, clothes, or outer gloves if contamination occurs
9. Use waterproof materials (e.g., waterproof aperture drapes) to limit spreading contaminated liquids

The techniques for treating patients with radioactive contamination and the techniques used to control infections (i.e., universal precautions) are similar. Following removal of the clothes and shoes, most of the residual contamination occurs on the hands, head, and neck. The priorities of decontamination depend on the type of radionuclides involved. High concentrations of β-emitters, corrosive acids, or fluorides produce skin injuries unless removed immediately. The physical and chemical form of the contaminant determines the contaminant absorption and elimination rates (e.g., hydrogen fluoride is a toxic disassociation product of uranium hexafluoride, UF_6). Otherwise, contaminated wounds and body orifices should be decontaminated first, followed by the areas of greatest skin contamination. Sampling sites for radioactivity include the nose, mouth, wounds, and baseline urine. Waterproof wound dressings and drapes should be used to limit the spread of radioactive contamination. Following irritation, wounds should be dried with sterile gauze and the gauze should be retained as a sample for the evaluation of radioactive contamination.

Decontamination should begin at the periphery of the contaminated area and proceed to the areas of highest contamination. Decontamination of mobile victims involves washing their hair first while bending over rather than placing them directly under a shower. Total body showering is typically recommended only for widespread skin contamination. All noncontaminated wounds must be covered with waterproof dressings to prevent contamination. In patients receiving whole-body doses exceeding 1 Gy, wounds should be closed as soon as possible because of the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

subsequent threat of poor wound healing and infectious complications. A contaminated wound should be rinsed with saline using conventional aseptic techniques with excision reserved for contamination by long-lived radionuclides (e.g., α-emitters). Decontamination of the skin should begin with the least irritating method and progress to more aggressive techniques if needed. The skin is an important barrier to the absorption of external contamination; therefore, decontamination techniques should avoid abrading intact skin.

The goal of decontamination is the reduction of the contamination levels to <2–3 times background levels or until the contamination is <10% of the initial level. The initial priority is the decontamination of open wounds with copious saline irrigation for at least 3–5 minutes. Multiple irrigations are usually necessary to remove the contamination from the skin and wound; however, more than two to three decontamination cycles are usually not needed. After each irrigation, the fluid and surrounding area should be monitored for residual radiation with the Geiger counter. Be careful to avoid contamination of Geiger counter probe by tightly taping a surgical glove around the head of the probe. Because most radioactive contamination settles on clothing, promptly remove and double bag all clothing, shoes, and personal effects into a trash bag marked as a radiation hazard. Alternative measures for persistent radioactivity in open wounds include 3% hydrogen peroxide irrigation and debridement. Wounds with small amounts of contamination may be closed if surgically indicated.

Shaving and extensive rubbing should be avoided because such maneuvers cause abrasions and erythema. If contamination persists on the skin, other decontamination methods include the use of Lava soap, Clorox, and an equal mixture of Tide and cornmeal. Shampoo the hair several times and rinse with lemon juice or a 3% aqueous solution of citric acid. Avoid splashing water in the eyes, nose, and ears. Streams of water should be diverted away from the medial canthus to avoid forcing contaminated fluid into the lacrimal duct. If contamination remains, the hair should be removed with clippers. Contamination of the mouth requires gentle irrigation and suction of the mouth with the mouth turned sideways or down. A nasogastric tube may be inserted into the stomach, and small aliquots of irrigating fluid should be used to lavage the stomach. Large aliquots of fluid may force the contaminated fluid through the pyloric sphincter.

Decontamination measures can stop when repeat decontamination does not reduce the radiation level, the contamination level is <2–3 times background radiation levels, or when further decontamination would produce more harm than benefit.[441] Most contamination on the skin resides in the upper horny layer; this contamination will slough off within a few days.[443] Deep debridement and excision are usually necessary only when explosions force contaminated material deep into the tissues.

Following the final decontamination procedure, the patient's body should be dried and a complete survey of the body by the Geiger counter performed. The patient is then transferred to a clean stretcher by new attendants, and a final radiation check is performed. Before departure from the decontamination area and after removing all protective clothing, each member of the decontamination team requires a complete survey for radioactivity followed by a shower and new clothing. Dead radiation victims should be placed in a body bag; the bodies are stored in a mobile chilling unit rather than the hospital morgue. Contaminated bodies cannot be cremated because fire does not destroy radioactive material.

Biological Dosimetry

The prognosis and treatment of a patient exposed to radiation depend on the absorption and distribution of the radiation dose in the body. The two types of dosimetry used to determine the absorbed radiation dose are the following: 1) physical dosimetry measuring physical changes in biological tissues or closely adjacent clothing and 2) biodosimetry of radiation-induced alterations in cellular constituents or function. The former includes optically stimulated luminescence, thermoluminescence, or electron paramagnetic resonance of tooth enamel, toenails, fingers, or clothing accessories, whereas the latter involves cytogenetic analysis of radiation-induced changes at the sub-cellular level (dicentric chromosome assay, cytokinesis-blocked micronucleus assay). The most common methods to determine individual radiation doses include time to onset/severity of nausea and vomiting, reduction of absolute lymphocyte count over the first few days after exposure, and the presence of chromosomal aberrations (dicentrics, ring forms, cytokinetic block micronucleus assays) in peripheral lymphocytes.[154] A radiation casualty management software program (Biological Assessment Tool) is available from the Armed Forces Radiobiology Research Institute (https://afrri.usuhs.edu/research-assessment-of-radiation-injury) to facilitate the recording and estimation of individual radiation doses.[444] The US Department of Health and Human Services Radiation Emergency Medical Management (REMM, https://remm.hhs.gov/) provides Internet access to patient management and a radiation dose estimator based on time to onset of vomiting and lymphocyte depletion kinetics with confirmation by the dicentric chromosome assay. A rough estimation (i.e.,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

triage score) of the radiation dose in a patient without trauma using the CBC and the presence (+2) or absence (0) is Equation 39.4. A triage score of >3.7 suggests a radiation dose of >1 Gy and the potential need for further evaluation.

$$\text{Triage score} = \%\ \text{neutrophils}/\%\ \text{lymphocytes} + \text{presence or absence of vomiting} \quad \text{(Equation 39.4)}$$

Changes in the lymphocyte count and cytogenetic analysis for chromosomal aberrations are more reliable prognosticators than physical estimates of whole-body radiation doses of >100 mSv for cytogenic analysis and of >250 mSv for lymphocyte counts.[445,446] Table 39.9 outlines the clinical findings and prognosis based on the absorbed dose of whole-body irradiation. These estimated doses are approximations that may vary by up to 25%. Most radiation exposures in uncontrolled setting occur nonuniformly; consequently, recovery may occur when estimated radiation levels predict a lethal hematological or gastrointestinal syndrome. Estimations of local radiation based on these techniques are much less precise compared with homogeneous total-body irradiation.

Symptoms

The onset and severity of the acute radiation syndrome are dose-dependent with a sigmoid dose-response curve above the threshold of the specific tissue; the organ-specific threshold depends on tissue radiosensitivity with dysfunction increasing as the dose increases until function ceases due to cell death. The most radiosensitive cells are rapidly proliferating with high metabolic activity including spermatogonia, lymphocytes, erythroblasts, and other hematopoietic cells; the exception are highly differentiated, mitotically inactive peripheral lymphocytes.[447] When present, early erythema and conjunctivitis suggest the spatial distribution of the ionizing radiation exposure. The chronology of signs and symptoms should be documented carefully with the aid of photographs as they become available. Table 39.35 displays the approximate onset and severity of clinical features associated with whole-body radiation doses exceeding 1 Gy. Mild nausea and mild headaches may occur following whole-body radiation exposures of <1 Gy; however, symptoms and signs are usually subclinical. Although survival is likely following exposure to radiation doses of 1–2 Gy, these patients may require antiemetics and correction of fluid/electrolyte imbalances. Evaluation of lymphocyte, polymorphonuclear leukocyte, and platelet concentrations provides more accurate measures of absorbed radiation at doses above 2 Gy than clinical symptoms.[154] Significant bone marrow damage occurs at whole-body doses of 2.5–5 Gy with progressive marrow hypoplasia followed by aplasia at 5–6 Gy. The $LD_{50/60}$ (i.e., dose causing 50% of the population to die in 60 days) is 3.5–4 Sv without medical treatment and occasionally 7–8 Gy with aggressive and skilled medical care.[116]

Blood

Following severe radiation exposures, the lymphocyte count declines rapidly within a few days. Blood should be collected immediately for hematological analyses (CBC with differential/platelet count – 1 lavender

TABLE 39.35. Approximate onset and severity of clinical features of acute radiation syndrome associated with exposure to whole-body radiation doses over 1 Gy and early clinical features of acute radiation syndrome manifest. Because these values are based on limited data (International Atomic Energy Agency, Armed Forces Radiobiology Research Institute, National Council on Radiation Protection and Measurements), decisions on prognosis of an individual should be based on all the data available, including lymphocyte depletion, clinical examination for the presence of trauma, medical history, and details regarding the radiation exposure (e.g., source, location, shielding). Clinical features of acute radiation syndrome are not unique; therefore, other etiologies for the signs and symptoms should be considered (e.g., occult infection, sepsis). Values in parentheses represent the incidence of symptom or sign. (Adapted from IAEA).[447]

Whole-Body Exposure (Gy)	Onset Emesis (Incidence)	Onset Diarrhea (Incidence)	Onset Headache (Incidence)	Altered Consciousness (Onset/Incidence)	Temperature (Onset/Incidence)
1–2 (Mild)	≥2 hours (10–50%)	None	Slight	None	Normal
2–4 (Moderate)	1–2 hours (70–90%)	None	Mild	None	Increased (1–3 hours/10–80%)
4–6 (Severe)	<1 hour (100%)	Mild 3–8 hours (<10%)	Heavy 1–3 hours (>10%)	None	Fever (1–2 hours/80–90%)
6–8 (Very severe)	<1/2 hour (100%)	Heavy 1–3 hours (>10%)	Severe 3–4 hours (80%)	Sometimes altered	High fever (<1 hour/100%)
>8 (Grave)	<1/6 hour (100%)	Heavy <1 hour (~100%)	Severe 1–2 hours (80–90%)	Unconscious (seconds-minutes/100% at 50 Gy)	High fever (<1 hour/100%)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

top tube), biochemical (serum chemistries – 1 red top tube), and cytogenetic (chromosomal analysis, HLA typing – 2 green top tubes); the lab should be consulted for transportation requirements (e.g., temperature, time, container). Chromosomal aberrations should be evaluated as soon as possible within the first few weeks after radiation exposure. Dicentrics and rings are unstable chromosomal features that progressively disappear over a few months or longer; therefore, extrapolation of radiation doses received in the distant past (years) using these techniques is inappropriate. Analysis of the peripheral blood (i.e., lymphocytes) for chromosomal aberrations preferably should occur within 6–8 weeks of exposure and usually requires approximately 3–4 days. Collection of blood for radioisotope analyses (1 red top, 2 lavender top tubes) is necessary only in the presence of internal contamination.

The CBC with differential should be repeated every 4–6 hours within the first 48 hours when the history indicates the possibility of serious whole-body irradiation. The appearance of lymphopenia during the first two days or prodromal symptoms (nausea, vomiting) within a few hours after exposure are the best early indicators of serious radiation exposure. The significance of lymphocyte depletion must be interpreted cautiously in the presence of major trauma and correlated to other measures of irradiation (e.g., chromosomal aberrations, accident reconstruction, prodromal symptoms). After the 4th postradiation day, daily hemograms are necessary for seriously poisoned patients (>2–4 Gy), whereas daily hemograms can begin after the 18th day for mild cases of acute radiation syndrome (1–2 Gy). Figures 39.5 and 39.6 demonstrate dose-related changes in the neutrophil and lymphocyte counts, respectively, over the course of the first 180 days postexposure. In the absence of medical treatment, mortality approaches 100% within 30 days following whole-body radiation exposures above 6 Gy, whereas survival is highly unlikely following exposures of 10 Gy with the best medical care.[118] Table 39.36 correlates prognosis with absorbed dose and minimal lymphocyte count during the first 48 hours after radiation exposure.

Early collection of blood for blood type and lymphocyte typing is important in seriously irradiated patients considered for bone marrow transplantation. Potential candidates for bone marrow transplantation require immediate HLA typing because of the rapid depletion of the lymphocytes necessary for HLA typing. The time and date of collection of the blood sample should be carefully recorded. The status of fluid and electrolyte balances determines the need for other serum chemistries (e.g., electrolytes, creatinine). The onset of anemia without suppression of other blood elements soon after radiation exposure suggests a bleeding source rather than bone marrow suppression.

Combined Injuries

Although the exact effect of combined thermal and radiation injuries is not well defined, animal models and the Chernobyl experience suggest increased lethality occurs when these two types of injuries occur simultaneously. Because most burns in Japanese atomic bomb survivors were minor (i.e., <10% total body surface), the radiation dose did not correlate well to thermal burns; however, the larger size of current bombs probably would produce much greater thermal injuries.[448] Reparative surgery including burn wound excision should be performed within the first 24–36 hours postexposure to reduce infectious complications; surgery should be avoided in the next several weeks after this 2-day time period. The treatment of radiation and thermal burns is similar to conventional burn treatment started after decontamination. Partial thickness burns should be treated with topical antimicrobial agents (e.g., silver sulfadiazine) and temporary skin substitutes followed by dry dressings. Prophylactic antibiotics are reserved for traumatic cutaneous wounds, selective decontamination, and early surgery.[449]

TABLE 39.36. Approximate correlation of minimal serum lymphocyte count during the first 48 hours after acute whole-body radiation exposure with prognosis. Death precedes cytopenia when the whole-body dose exceeds 50 Gy. (Adapted from Mettler and Voelz).[118]

Minimal Lymphocyte Count/mm^3	Absorbed Dose[a] (Gy)	Injury Severity	Prognosis
1,500–3,000	0–0.4	None clinically apparent	Excellent
1,000–1,499	0.5–1.9	Clinically significant, death unlikely	Good
500–999	2.0–3.9	Severe	Fair
100–499	4.0–7.9	Very severe	Poor
<100	≥8	Grave	Death likely

[a] Approximate.

Referrals/Relocation

Victims receiving >2 Gy of whole-body radiation exposure in Classes I–IV should be transferred to a facility capable of evaluating and treating bone marrow failure. US resources for the treatment of radiation injuries include the Radiation Emergency Assistance Center/Training Site (REAC/TS) in Oak Ridge, Tennessee (emergency telephone line: 865-576-1005; website: https://orise.orau.gov/reacts/index.html), US Department of Health and Human Services (DHHS) Radiation Emergency Medical Management (REMM) (website: https://remm.hhs.gov/), and the Chemical/Biological Hotline of the National Response Center (phone: 300-424-8802).[450] The Radiation Injury Treatment Network (RITN) is a national network of over 70 medical centers that specialize in the management of bone marrow failure and the health consequences (e.g., chelation, decontamination) associated with acute radiation syndrome (https://ritn.net/treatment/). Typically, the local population adjacent to a nuclear incident should remain indoors when the radiation dose exceeds 10 mSv (1 rem); evacuation for 1 week is recommended for population exposure exceeding 50 mSv (5 rem).[451] Temporary relocation is recommended when the estimated radiation exposure exceeds 30 mSv (3 rem) during the first month or 10 mSv (1 rem) during subsequent months. Population exposures exceeding a lifetime dose of 1 Sv (100 rem) indicate the need for permanent resettlement.

Supplemental Care

Thyroidal Blocking Agents

Following a nuclear detonation, internal contamination with radioiodine (^{131}I, ^{125}I) from fallout is a common cause of radiation exposure. ^{131}I is a fission product of uranium. Sources of radioiodine exposure include inhalation of contaminated particles or aerosols and/or the ingestion of contaminated substances (water, vegetation, meat, milk, and other dairy products from cows grazing on radioiodine-contaminated vegetation). Based on the Chernobyl experience, children are especially susceptible to radioiodine effects because of their high milk consumption and their active thyroid glands.[64] The timely ingestion of potassium iodide effectively blocks radioiodine uptake and reduces the subsequent risk of developing thyroid nodules and cancer. Local officials typically determine the need for the prophylactic use of potassium iodide (KI) following the release of this radionuclide.[452]

The efficacy of KI is time-dependent with the largest reduction of radioiodine accumulation in the thyroid resulting from KI ingestion prior to or within several hours of internal radioiodine contamination. Modeling studies of euthyroid adults suggest potassium iodide (KI) effectively reduces environmentally dispersed radioiodine accumulation in the thyroid when administered 48 hours preexposure to 8 hours postexposure. The blockage of radioiodine uptake decreases substantially a few hours postexposure depending on the amount of iodine in the diet. The protective effects of potassium chloride decrease to 80% 2 hours after ^{131}I exposure and 40% 8 hours after ^{131}I exposure in individuals with iodine sufficient diets.[453] For individuals with iodine-deficient diets, the protective effects of potassium iodide decrease to ~65% and ~15%, respectively, in those times. The ingestion of potassium iodide concurrently with radioiodine exposure blocks 97% of the internal contamination.[454,455] The protective effects of potassium chloride are minimal if ingested 96 hours prior to ^{131}I exposure or 16 hours after ^{131}I exposure.

Treatment should continue for a minimum of 3 days; KI administration >10 days postexposure is not efficacious unless radioiodine exposure continues. The decision to use potassium iodide should be individualized depending on age and time since exposure.[456] Adults >40 years of age usually do not benefit from KI unless the projected thyroid dose exceeds 5 Gy, whereas infants and children may benefit from KI use following thyroid radiation doses of >10–100 mSv. The daily adult KI dose is 130 mg, whereas the dose for children under 70 kg and 3–18 years old is 65 mg, 32 mg for children 1 month to 3 years of age, and 16 mg for infants <1 month of age. Contraindications to KI use include acute hyperthyroidism, dermatitis herpetiformis, and iodine hypersensitivity. Anaphylactoid reactions to radiocontrast material, seafood allergies, and allergic contact dermatitis from iodine-containing antibacterial preparations are not necessarily IgE antibody-mediated iodine hypersensitivity. Nausea and vomiting are the most common side effects; rash occurs occasionally.

Radioprotectors

These agents are primarily free radical scavengers; experimental evidence suggests these agents provide some protection when administered before radiation exposure. The US Food and Drug Administration (FDA) has not approved any safe, effective countermeasures for the prevention of acute radiation syndrome.[457] The FDA approved the intravenous use of amifostine [*S*-2-(3-aminopropylamino) ethylphosphorothiotic acid, WR-2721] only in radiotherapy patients because of significant potential adverse effects associated with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

prophylactic use.[458] Amifostine is a thiol compound that reduces oxidative stress by acting as a free radical scavenger when administered 15–30 minutes prior to radiation exposure; clinical uses include the prevention of renal dysfunction from cisplatin therapy and xerostomia (dry mouth) following head and neck radiotherapy.[459] Radiation induces biochemical injuries within nanoseconds; no specific therapy can reverse the subsequent sequence of events; consequently, radioprotectors are effective only when administered prior to the radiation exposure. During the US Army's Antiradiation Drug Development Program testing of the phosphorothioate class of radioprotectors including amifostine (WR-2721), the latter was the most effective based on enhanced protection for bone marrow and the gastrointestinal tract, resulting in decreased LD_{50} in animal studies.[460] However, the inability to penetrate the blood–brain barrier restricts any effect on radiation-induced central nervous system damage.[461] Although amifostine is approved by the Food and Drug Administration (FDA) for patients undergoing radiotherapy, serious side effects (e.g., nausea, vomiting, hypotension, hypocalcemia, nephrotoxicity) limit the use of this intravenous drug in emergency personnel participating in vigorous activities.

Elimination Enhancement

Chelating Agents

The primary use of chelating agents (calcium diethylenetriamine pentaacetate, Ca-DPTA, CAS: 12111-24-9; zinc diethylenetriamine pentaacetate, Zn-DTPA, CAS: 125833-02-5) is the intravenous treatment of internal contamination by transuranic elements (americium, plutonium, curium).[118] The intravenous adult loading dose of Ca-DPTA is 1 g (14 mg/kg in children <12 years) as soon as possible after exposure followed by a daily maintenance dose of 1 g (14 mg/kg in children) of Zn-DPTA over days to months, depending on the amount of internal contamination. These US FDA-approved drugs are administered to enhance the elimination of these radionuclides; data are limited regarding the efficacy of these drugs to improve survival from exposure to high ionizing radiation doses. Typically, americium, curium, and plutonium are not released during a nuclear detonation. Serum trace metals (magnesium, manganese, zinc) should be monitored during long-term therapy.

Prussian Blue

Insoluble Prussian blue (Berlin blue, ferric ferrocyanide, ferric hexacyanoferrate II, iron blue) disrupts the enterohepatic recirculation of radioactive cesium and thallium, resulting in the increased elimination of these radionuclides via ion exchange; other radionuclides do not respond to this compound.[462] This compound is a USFDA-approved treatment for internal contamination by radioactive cesium and thallium. The indication for Prussian blue is ingestion of *10 times* the annual limit of ^{137}Cs intake (3.7 MBq, 100 μCi by ingestion; 7.4 MBq, 200 μCi by inhalation), whereas the need for treatment of ^{137}Cs exposures 1–10 times the annual limit is controversial. Below the annual limit of ^{137}Cs, treatment is unnecessary.

Relative contraindications include poor gastrointestinal motility and intestinal obstruction; potential adverse effects include electrolyte imbalance, constipation, and reduced bioavailability of some orally administered drugs. The amount of cyanide released by Prussian blue is not clinically significant with no reported cases of cyanide poisoning reported in the medical literature.[463] The adult dose is 3 g by mouth three times daily while maintaining a high-fiber diet and laxatives as needed, whereas the dose for children 2–12 years of age is 1 g three times daily. Higher Prussian blue doses were used for internal contamination during the Goiania accident.[464] Food may enhance fecal elimination following administration of Prussian blue. The minimum duration of treatment is 30 days with cessation of treatment determined by the amount of radionuclide eliminated from the urine and feces. The colored dye, soluble Prussian blue, is not an effective substitution for the insoluble form of Prussian blue.

Antacids/Cathartics

Aluminum-containing antacids should be administered when internal contamination with strontium isotopes is suspected. For large radionuclide ingestions within the last few hours, the administration of cathartics is an option to decrease gastrointestinal transit time;[435] however, the effectiveness of this procedure is unproven.

Definitive Care

Radiation countermeasures include radioprotectors, radiomitigators, and radiation therapeutics. Radioprotectors (amifostine; γ-tocotrienol, a vitamin E isomer) are prophylactic agents administered prior to radiation exposure to prevent subsequent tissue injury during the early phase of deterministic effects. These agents are free radical scavengers that reduce the damage from ionizing radiation-induced oxidative stress. Radiation mitigators administered after the radiation exposure and prior to overt symptoms of acute radiation syndrome stimulate the recovery of damaged tissues. These agents include 5-androstenediol,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

truncated flagellin (CBLB502), interleukin-12, G-CSF (filgrastim, Neupogen®), PEGylated G-CSF (pegfilgrastim, Neulasta®; pegfilgrastim-cbqv, Udenyca®), GM-CSF (sargramostim, Leukine®), and angiotensin-converting enzyme inhibitors (captopril).[465] USEPA-approved radiation therapeutics ameliorate radiation-induced symptoms after presentation and accelerate tissue regeneration only prior to the onset of symptoms including G-CSF, PEGylated G-CSF, and GM-CSF.[119,466] These drugs do not improve thrombocytopenia. Romiplostim (Nplate®) is a thrombopoietin receptor agonist approved by the USEPA for the treatment of ARS in adults including pregnant and lactating women as well as children.

Supportive Measures

Supportive care (e.g., fluids, electrolytes, antimicrobials, antiemetics, antidiarrheal agents, analgesics, topical burn creams, isolation precautions, transfusions) improves survival, the effectiveness of myeloid cytokines, and the chances of spontaneous hematological recovery after exposure to radiation levels up to 5–7 Gy within 1–2 months of radiation exposure, depending on the presence of other radiation syndromes. In patients administered supportive care within 24 hours of radiation exposure, the $LD_{50/60}$ increases from ~3.5–4 Gy to ~6–7 Gy.[467,468] Following exposure to low radiation doses, vomiting usually ceases after 48–72 hours with prolonged antiemetic therapy unwarranted. Infection and hemorrhage resulting from the reduction of the granulocytes and platelets are the primary lethal complications of the hematological syndrome. The management of serious radiation exposure, bone marrow aplasia, and immune system depression is similar. Table 39.37 correlates the whole-body radiation dose with clinical features, medical treatment, and lethality based on relatively uniform radiation exposure.

Supportive care includes early evaluation of fluid and electrolyte balance, antiemetics, and reassurance to help alleviate the natural fears associated with radiation exposure. 5-Hydroxytryptamine (HT)-3 receptor antagonists (e.g., ondansetron, Zofran®; granisetron, Kytril®; dolasetron, Anzemet®; palonosetron, Aloxi®) are typically more effective for radiation-induced emesis than phenothiazine compounds (e.g., prochlorperazine, chlorpromazine); these compounds do not protect normal tissues from radiation injuries.[116] Although less data (e.g., prospective clinical trials) are available to evaluate the efficacy of dexamethasone or neurokinin (NK)-1 receptor antagonists for radiation-induced vomiting compared with 5-HT-3 receptor antagonists, some studies suggest these medications are effective antiemetics for the acute radiation syndrome-induced nausea and vomiting. Potential treatment of diarrhea includes the use of loperamide, anticholinergics, or aluminum hydroxide suspension (e.g., Amphojel®). Adult Respiratory Distress Syndrome (ARDS) is a common complication of serious burn injuries; the mixed venous pO_2 should be maintained above 35 mm Hg. A baseline electrocardiogram, electroencephalogram, urinalysis, and slit lamp examination are helpful measures to establish a baseline for the later evaluation of the potential development of radiation-induced damage to the respective areas of the body.

Mucositis

Oral mucositis is a multifactorial pathological process involving proinflammatory cytokines, oral microbes, reactive oxygen species, and second messengers that cause mucosal pain and ulceration. Antibiotic administration does not prevent radiation-induced mucositis; however, sucralfate mouthwashes improve symptoms

TABLE 39.37. Approximate correlation of whole-body radiation dose to prognosis and medical treatment. Radiation exposure is frequently nonhomogeneous; therefore, these values are estimates, and the prognosis may be better than predicted following nonuniform radiation exposure. (Adapted from IAEA).[447]

Whole-Body Dose (Gy)	Clinical Features	Lethality (Onset)	Medical Response
1–2 (Mild)	Fatigue, weakness	0	Supportive care
2–4 (Moderate)	Fever, infections, bleeding, weakness, epilation	0–50% (6–8 weeks)	Special supportive measures days 14–20 with isolation days 10–20
4–6 (Severe)	High fever, infections, bleeding, epilation	20–70% (4–8 weeks)	Special supportive measures days 7–10 with isolation from beginning of hospitalization
6–8 (Very Severe)	High fever, diarrhea, vomiting, dizziness, disorientation, hypotension	50–100% (1–2 weeks)	Special supportive measures from start of hospitalization
>8 (Grave)	High fever, diarrhea, unconsciousness	100% (1–2 weeks)	Symptomatic care

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and Biotene® reduces the risk of mucositis and improves dry mouth associated with radiation-induced mucositis.[469] Palifermin (keratinocyte growth factor-7) is the only pharmacological drug approved for the reduction of radiation-induced mucositis with therapy beginning 3 days before irradiation. This recombinant *N*-terminal truncated keratinocyte growth factor stimulates reparative proliferation of epithelial cells in a variety of tissues by interacting with the cognate receptor fibroblast growth factor recerptor-2B.[470] Episil, GelClair, Caphosol, and MuGard are topical palliative rinses approved for the control of mucositis-related symptoms; however, the efficacy of these treatments is controversial.[471] Magic mouthwash is a rinse commonly compounded from topical anesthetics (Benadryl or viscous lidocaine), a muco-adherent vehicle (milk of magnesia, Kaopectate), and other agents (steroids, antifungals, antibiotics) for pain management.[472]

Enteritis

Acute radiation enteritis results from damage to rapidly dividing intestinal epithelium (e.g., crypt stem cells) that disrupts the intestinal barrier, allowing the translocation of intestinal bacteria.[473] The subsequent interference with the Na^+/K^+ pump impairs sodium/chloride absorption, producing watery diarrhea. Chronic radiation enteritis causes progressive obliterative endarteritis causing fibrosis and bowel ischemia, manifesting as strictures, fistulae, perforations, abscesses, and hemorrhage.[474] Treatment strategies involve symptom relief, diagnosis/management of intestinal complications, and limiting fibrosis to prevent organ damage.[475]

Dietary modifications include elimination of fatty and high-residue diets, identification of lactose intolerance, and treatment of bile acid malabsorption with cholestyramine. Complications (e.g., strictures, obstruction, fistulae, perforations) of radiation enteritis typically are treated with surgery; however, surgical complications are common because of the increased risk of anastomotic leaks. The theoretical advantages of using probiotics to prevent or treat radiation enteritis include the reduction of oxidative stress, downregulation of adhesion molecules, and release of glutathione. Although some studies demonstrate reduced frequency and/or severity of medical radiation-induced enteritis in patients treated with probiotics, evidence for the efficacy of probiotics in this setting is inadequate.[476] Experimental therapies include the use of pentoxifylline and tocopherol,[477] anti-inflammatories (e.g., methylprednisolone, sulfasalazine), octreotide, hyperbaric oxygen,[478] and heparin-binding epidermal growth factor.[475]

Hematological Subsyndrome

Treatment of the hematopoietic syndrome involves the use of blood transfusions for cytopenias (anemia, neutropenia, thrombocytopenia), administration of hematopoietic cytokines or growth factors (granulocyte colony-stimulating factor, G-CSF; granulocyte-macrophage colony-stimulating factor, GM-CSF, recombinant human granulocyte-macrophage colony-stimulating factor (rhGM-CSF, or Leukine®), and transplantation of allogeneic histocompatible donor-matched bone marrow cells or stem-cell transplantation in selected cases.[479] Blood transfusions may be necessary 2–4 weeks after radiation exposure when the radiation dose is sufficiently high (>2–3 Gy) to limit the effectiveness of cytokines. Recovery from the hematological syndrome depends on prevention and/or successful treatment of hemorrhage, bone marrow failure, and infection in the immunocompromised patient until hematopoietic cell lineages (pluripotent stem cells, progenitor blood cells) replenish the bone marrow.

Transfusions

Transfusions of cellular blood elements (e.g., platelets, packed erythrocytes) are necessary for patients with severe bone marrow damage, typically after trauma or 2–4 weeks after radiation exposure. Adequate platelet replacement is particularly important in patients with thermal trauma or cutaneous radiation syndrome. The platelet count should be maintained above 20×10^3 cells/μL with platelet products, reduced white cells (leukoreduction), and irradiated with 15–25 Gy to prevent transfusion-associated graft-vs.-host disease.[445] These precautions reduce the risk of allosensitization, transmission of viral infections, and graft-vs.-host disease;[480] the presentation of the latter and radiation-induced organ toxicity is similar (fever, skin rash, desquamation, server diarrhea, pancytopenia, hyperbilirubinemia). To reduce postoperative complications, the preoperative platelet count should be $>75 \times 10^9$ cells/L. In patients without an obvious need for a bone marrow transplant, the use of random-donor blood products matched for ABO and Rh compatibility is recommended for logistical reasons. HLA-compatible platelet transfusions may be required if refractoriness develops to random-donor platelets. Red cell concentrates and fresh frozen plasma should be infused only as required to maintain perfusion; these products should also be irradiated. Prophylactic or therapeutic uses of granulocyte transfusions probably are not efficacious.[481]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Cytokines

Radiomitigators for the hematological subsyndrome are filgrastim (G-CSF, Neupogen®), PEGylated filgrastim (PEG-CSF, Neulasta®; pegfilgrastim-cbqv, Udenyca®), and sargramostim (Leukine®). These colony-stimulating myeloid cytokines enhance neutrophil function (e.g., microbicidal activity) and recovery by improving the survival, amplification, and differentiation of granulocyte progenitors in neutropenic patients;[482] the treatment of radiation-induced and chemotherapy-induced neutropenia is similar. Whole-body radiation exposures exceeding 2 Sv suggest the need for cytokines and/or colony-stimulating factors; colony-stimulating factors should be started as soon as possible after radiation exposures of >2–3 Gy up to 6–10 Gy depending on the presence of other injuries (blunt trauma, burns, comorbidities), severities of hematotoxicity, age (>60 years, <12 years), resources (e.g., < or > 100 causalities), and likelihood of recovery.[154] The early use (1–3 days postexposure) of rhGM-CSF or G-CSF is indicated for patients absorbing large radiation doses (i.e., ~4–8 Gy) sufficient to produce prolonged neutropenia with a good prospect for eventual recovery from bone marrow depression.[445] Although most studies use human recombinant G-CSF, G-CSF is not species-specific. Colony-stimulating factors should be continued throughout the time of recovery until the neutrophil count reaches a level >1,000 cell/μL above the nadir. The subcutaneous dose is similar for radiation- and chemotherapy-induced neutropenia.

Molecular cloning and formulation of recombinant human colony-stimulating factors offer a potential tool to ameliorate the hematological damage in radiation victims. Granulocyte colony-stimulating factor (e.g., G-CSF, filgrastim, Neupogen®), recombinant human pegylated G-CSF (pegfilgrastim, Neulasta®), recombinant human granulocyte-macrophage colony-stimulating factor (rhGM-CSF, sargramostim, Leukine®) erythropoietin (stimulation of erythropoiesis), and interleukin-3 (IL-3) are available for experimental and clinical studies. Sargramostim, pegfilgrastim, and filgrastim are approved by the US FDA as medical countermeasures to treat patients with radiation-induced myelosuppression following a radiological/nuclear incident when administered up to 48 hours after exposure.[483] These three countermeasures are included in the US Strategic National Stockpile of medical equipment and pharmaceuticals. Although erythropoietin and IL-3 are not US FDA-approved for radiation accidents, previous use in radiation accidents suggests some efficacy.[484,485] These cytokines do not treat thrombocytopenia. Romiplostim (Nplate®) is a thrombopoietin receptor agonist approved by the USEPA for the treatment of ARS in adults including pregnant and lactating women as well as children. Knowledge of the risks and benefits is not well-defined to determine the exact role of these agents for prevention of infection and survival of radiation victims; however, filgrastim and pegfilgrastim should be considered in patients with radiation exposure of >2 Gy, significant or prolonged neutropenia (<500 cells/mm^3), or extremes of age (<12 years, >60 years), preferably within 24 hours of radiation exposure.[479] Potential adverse effects include drug-related fever, rash, gastrointestinal upset, myalgias, hypoxia, and thromboembolism, whereas rare complications associated with use of G-CSF include splenic rupture, hypersensitivity reactions (*Escherichia coli*-derived proteins), sickle cell crises, Sweet's syndrome, myelodysplasia, and myeloid malignancy.[486] The causation of these rare complications remains unclear. The typical adult dose of filgrastim is 10 μg/kg/day as a subcutaneous injection, whereas the initial adult subcutaneous dose of pegfilgrastim is 6 mg 1 week apart for 2 doses. Some data suggest loratadine may reduce the bone pain associated with the latter, but the evidence is limited. These agents are usually started as soon as possible following suspected or confirmed radiation exposure exceeding 2 Gy and continued until the absolute neutrophil count exceeds 1,000. Acute radiation syndrome countermeasures with US FDA investigational new drug (IND) status include genistein (BIO 300, radioprotector/radiomitigator), entolimod (CBLB502, radioprotector/radiomitigator), AEOL 10150 (meso-porphyrin, radiomitigator), beclomethasone 17,21-dipropionate (OrbeShield®), recombinant interleukin-12 (HemaMax, radiomitigator), myeloid progenitor cells, and ONO1210 (chlorobenzylsulfone kinase inhibitor, radiomitigator).[119,487]

The European METREPOL (Medical Treatment Protocols for radiation accident victims) recommends the use of G-CSF and keratinocyte growth factor (KGF) for 14–21 days as soon as possible after exposure; however, there is no consensus on the use of erythropoietin, thrombopoietin, thrombopoietin receptor agonists, or stem cell factors.[488] Common complications of G-CSF administration include headache, arthralgias, and fatigue, whereas life-threatening complications (stroke, myocardial infarction, splenic rupture) are rare.[489] Hematopoietic stem cell transplantation is recommended only when severe aplasia persists despite cytokine treatment. An rhGM-CSF infusion increased the granulocyte count in five patients exposed to 2.5–6 Gy of internal and external ^{137}Cs irradiation in Goiania, Brazil; however, the exact contribution of the rhGM-CSF to survival of these patients is unclear.

The red cell and platelet counts did not increase after treatment.[490]

Toxic effects of rhGM-CSF include fluid retention, thrombophlebitis, pericarditis, capillary leak syndrome, pulmonary infiltrates, and various side effects (e.g., myalgias, arthralgias, low-grade fever, anorexia).[491] In contrast to using G-CSF that increases the granulocyte count without reducing neutrophil migration, rhGM-CSF reduces neutrophil migration into injury areas. Therefore, the latter compound is theoretically a better choice for radiation-induced injuries complicated by burn trauma. In animal models, IL-3 and rhGM-CSF act synergistically to increase granulocytes without reducing neutrophil migration.[492]

Stem Cells and Transplantation

Currently, there is no consensus on the role of hematopoietic stem cell transplantation in the treatment of ARS. Matched, related, and unrelated allogeneic stem-cell transplantations are potentially curative in patients with certain predominately hematological cancers; however, the efficacy of this procedure in radiation victims is less clear. Although stem cell transplants may prolong survival following autologous hematopoietic recovery, radiation-induced injury to other organs usually limits survival. [493] Many radiation victims recover from hematopoiesis without a bone marrow transplant because of the wide distribution and resilience of red marrow stem cells, the likelihood of nonuniform irradiation, and the ability of remaining stem cells to repopulate the whole hematopoietic system. Mesenchymal stem cells are a heterogeneous population of multipotent stromal cells found in various tissues (adipose, dermal, placental, umbilical cord), blood vessels, and the kidney; these stem cells lack hematopoietic surface proteins. Although these stem cells are relatively radioresistant, clinical data are inadequate to define their role in the treatment of radiation-induced damage.[494]

Depending on radiation exposure severity, bone marrow biopsy should be taken from different sites 24 hours after exposure and repeated as needed. Bone marrow transplantation has a limited role in the treatment of radiation victims because this procedure benefits only those patients receiving whole-body radiation doses of 6–10 Sv without comorbid conditions (i.e., irreversible damage to lungs, kidneys, gastrointestinal tract); spontaneous recovery of the bone marrow will not occur in these patients without transplantation. The presence of 500 granulocytes/μL and $>100 \times 10^3$ platelets/μL at 6 days postexposure suggests residual hematopoiesis without the need for stem-cell transplantation.

At radiation doses exceeding 8 Gy, a radiation pneumonitis occurs ~3–7 months postexposure.[495] Radiation doses of >8–12 Gy produce severe gastrointestinal toxicity, resulting in damage to mucosal epithelial cells, sepsis from enteric bacteria, and extensive diarrhea. Consequently, bone marrow transplants in patients absorbing these whole-body doses are usually not successful because of radiation pneumonitis, gastrointestinal necrosis, infectious complications from altered immunity and mucocutaneous barriers, and/or hepatorenal failure.[118,496] Following the Chernobyl accident, 6 transplants of fetal livers and 13 transplants of allogenic bone marrow grafts (7 HLA identical, 6 haploidentical donors) were performed 4–16 days postexposure.[497] The 13 patients received bone marrow transplants after absorbing estimated whole-body radiation doses of 5.6–13.4 Gy. The two survivors received haploidentical bone marrow from their sisters after receiving estimated radiation doses of 5.6 and 8.7 Gy; both patients rejected the transplant ~1 month after transplantation.[64] There were 16 survivors in the group of 43 victims receiving whole-body radiation doses of 4–6 Gy; only 1 survivor in the group received >6 Gy. The other 11 victims died of associated injuries (e.g., burns, interstitial pneumonitis, graft-vs.-host disease, acute renal failure, and adult respiratory distress syndrome).[493]

Complications of bone marrow transplantation include graft rejection, graft-vs.-host disease (GVHD), and opportunistic infection, particularly cytomegalovirus interstitial pneumonitis. The administration of G-CSF shortly after a bone marrow transplant theoretically increases the risk of GVHD. The best candidates for transplantation are young victims with relatively uniform radiation exposure in the range of 7–10 Gy and available human leukocyte antigen (HLA)-identical sibling or close family donors.[153] Few patients over 50 years of age survive bone marrow transplantation.[498] Analysis of the potential role of bone marrow transplantation is complex, depending on patient and accident characteristics. The most effective range of radiation doses for survival after bone marrow transplantation probably ranges from 8–12 Gy, depending on the uniformity of the radiation dose.[497] Below this range, the Chernobyl experience complicated by extensive β-radiation burns suggests bone marrow transplantation adversely impacts survival; above this range, radiation-induced damage to other organs is probably fatal. Animal data indicate the optimum time of transplantation is the first 3–5 days postexposure when immunosuppression peaks. Waiting more than 1 week may require chemotherapy; this treatment increases the risk of opportunistic infections.[445] The experience at Chernobyl suggests bone marrow

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. transplantation is a more viable option for victims exposed to 8–12 Gy than fetal liver transplantation.

Infectious Complications

Most patients with granulocytopenia of <500 cells/μL for >5 days develop infections;[499] patients with granulocytopenia of <100 cells/μL are particularly susceptible to fatal gram-negative bacteremia. Although granulocytopenia is a major cause of increased susceptibility to infection in patients exposed to radiation, other cell and humoral agents may contribute to the increased susceptibility. In these patients, infections often occur in areas of the body where there is damage to the normal anatomic barrier that protects the body from invasion by microbes. The most common causes of infection in granulocytopenic patients are the aerobic gram-positive cocci (e.g., *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus* species) and the aerobic gram-rods (e.g., *Pseudomonas aeruginosa*, *E. coli*, *Klebsiella pneumoniae*).[500] Typical prophylactic regimens include fluoroquinolones with streptococcal coverage (penicillin or penicillin congener), antiviral drugs (acyclovir or congener), and antifungal agents (e.g., fluconazole). These regimens are continued until the absolute neutrophil count exceeds 500 cells/μL or the patient develops neutropenic fever. The blunting of the normal inflammatory response in patients with aplastic bone marrow and few circulating granulocytes requires careful, repeated physical examinations and serial X-rays to identify sources of infection. Among *febrile* patients with granulocytopenia, the etiology of the fever is equally divided between bacteremia, documented infection without bacteremia, clinically identified site of infection without specific pathogen, noninfectious origin, and fever of unknown origin.[500] Subsequent antibiotic therapy is directed at the suspected pathogen based on the recommendation for treating neutropenia and fever.

Prophylaxis Most seriously injured victims at Chernobyl received whole-body radiation doses compatible with bone marrow recovery following intensive supportive measures.[2] These patients received isolation with laminar airflow, prophylactic oral antibiotics, and systemic antimicrobial therapy when fever developed. Antibiotics are not usually required during the initial 7–10 days after radiation exposure. There were no deaths from infection among Chernobyl victims except for patients with graft-vs.-host disease, extensive burns, or radiation-induced enteritis.[64] Fluoroquinolones along with penicillin or other Streptococcal coverage are typically recommended for prophylactic treatment during the neutropenic period with gram-negative coverage added and fluoroquinolones withdrawn when fever develops.[154] Although there are no guidelines specifically for irradiated patients, most physicians use the guidelines formulated for neutropenia from nonradiation causes.[501]

Table 39.38 outlines prophylactic measures for the reduction of infection risks in granulocytopenic patients. Granulocytopenic patients with neutrophil counts of <100 neutrophils/μL require aggressive supportive care and prophylactic treatment, whereas patients with neutrophil counts above this level demonstrate substantially less risk of serious infection. The presence of associated traumatic injuries worsens the prognosis for granulocytopenic patients. Important measures to reduce the load of pathogens include water treatment (e.g., acidification) as needed, diets (e.g., use of canned foods, elimination of leafy green vegetables, citrus fruits, and tomatoes) with low microbial counts, frequent handwashing, use of gloves, and laminar airflow to eliminate *Aspergillus* contamination. The reduction of food and environmental pathogens is as important as the use of gowns, masks, and booties because most acquired infections result from contact with the hands of medical personnel or environmental contamination (i.e., air, water, food).[500]

Maintaining gastric acidity by the avoidance of antacids and H_2-antagonists is a theoretical measure to reduce stomach colonization and the frequency of aspiration pneumonia from nosocomial infections. Administration of sucralfate or prostaglandin analogs helps prevent gastric hemorrhage without increasing the gastric PH. The radiation dose and the status of gastric emptying determine the decision to administer drugs or food orally. Early (within 12 hours) enteral nutrition appears superior to total parenteral nutrition to maintain gastrointestinal mucosa and structure, stimulate gut recovery and immune function, and decrease bacterial invasion of the gut mucosa.[502] However, the decision to insert thin-bore feeding tubes into the duodenum may result in mucosal ulcerations in severely granulocytopenic patients; therefore, total parenteral nutrition may be preferred over enteral nutrition in these patients.

Meticulous attention to the use of catheters and dental hygiene are important measures to reduce the spread of nosocomial infections. Surgical implantation of a subcutaneously tunneled central venous catheter with meticulous protection of the catheter site (chlorhexidine, water-tight dressings) helps reduce invasive procedures. Although total microbial suppression allows colonization of hospital-acquired bacteria, oral antibiotics reduce the aerobic bacteria and fungi

TABLE 39.38. Reduction of infection risks in immunocompromised patients when feasible. (Adapted from Browne et al.).[445]

Goal	Action	Example
Reduce invasive procedures		Nasogastric tubes
Colonization-resistant inert surfaces		
Reduce microbial contact	Contact control	Handwashing
	Water treatment	
	Food	Low microbial diet
	Laminar air flow	↓ *Aspergillus* infections
↓ Microbes	Suppress microorganisms	
	Selective decontamination in neutropenic patients (<1,000/μL)	Oral nonabsorbable anti-bacterials that preserve anaerobes (fluoroquinolones)
	Anthelminthics if indicated	
	Monitor for resistant bacteria	
	Consider antivirals	
Physiological intervention	Maintain gastric acidity	Avoid antacids and H_2 blockers
		Sucralfate, Biotene® mouthwashes, or stress ulcer prophylaxis
		Early oral enteral nutrition as indicated
Personal hygiene	Povidone-iodine/chlorhexidine for skin disinfection	Soft toothbrushes
	Shampoo	
	Oral hygiene	Brushing, careful flossing
Host defenses	Active vaccinations for expected pathogens	Influenza, *Streptococcal* pneumonia
	Immunomodulators	

without inhibiting the anaerobic bacteria.[503] Because these drug regimens require 7–10 days to become effective, suppressive drugs should be started before the granulocyte count falls to levels of <100 neutrophils/μL. Prophylactic oral acyclovir is a standard antiviral agent for antibody-positive, granulocytopenic radiation victims. The use of cytokines improves the antibacterial activity of surviving immune cells and helps replenish lost cells.

Treatment The management of suspected infections in irradiated patients and other febrile, neutropenic patients is similar. Neutropenia alone does not require treatment, although selective decontamination of the gut is probably efficacious for severely neutropenic (<100 neutrophils/μL) patients. Knowledge of recent infection sources in the patient and hospital is an important determinant of the antibiotic regimen because most infections are hospital-acquired.[500] Iatrogenic factors (e.g., urinary catheters, exit site or tunnel infections from intravascular catheters, contamination from the administration of blood products, trauma) are potential sources of hospital-acquired infections.

Patients with neutropenia and fever (>37°C) should be treated promptly with an empirical regimen of antibiotics based on the bacterial susceptibility of nosocomial infections at the hospital and the physician's judgment. Typically, combination antibiotic therapy is administered with a broad-spectrum β-lactam-resistant penicillin or later generation cephalosporin plus an aminoglycoside. Vancomycin should be added to the antibiotic regimen if resistant gram-positive bacteria develop. Monotherapy with antibiotics (e.g., imipenem, ceftazidime) is appropriate for patients with neutrophil counts of >100 neutrophils/μL. Amphotericin B (0.5 mg/kg/day) should be added to the antibiotic regimen if the fever persists for more than 7 days after antimicrobial therapy was initiated. First-line antifungal therapeutic agents include amphotericin B, itraconazole, and voriconazole.[504,505] Antimicrobial treatment should continue at least while the patient is febrile. Radiation-induced activation of herpes simplex virus was a major complication in the Chernobyl victims exposed to high radiation doses; the viral infection responded to acyclovir.[2] Ganciclovir and high-dose γ-globulin are experimental therapies for the devastating cytomegalovirus pneumonitis.

Local injuries

Treatment of localized radiation injuries after decontamination and medical stabilization includes prophylaxis against infection (topical antibiotics), pain control (non-steroidal anti-inflammatory drugs, opioids, sedatives), anti-inflammatory creams (e.g., linoleic acid), topical steroids, topical antihistamines, careful

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. debridement of devitalized tissue, protection from traumatic injury, and vasodilator therapy; more serious cases may require grafting, bilaminate skin substitute, plastic surgery, or amputation.[118] Autologous keratinocytes and allogeneic stem cell administration may follow excision of affected tissue to prevent recurrent skin necrosis.[506] Fluid losses, bleeding, and infection 2–4 weeks after exposure to large cutaneous radiation doses are the primary causes of death. Initial fluid resuscitation is an important measure in the first few days to maintain circulation. Intravenous catheters should be inserted early in nonburn areas and maintained carefully to avoid colonization by nosocomial bacteria. The temperature should be closely monitored for evidence of hypothermia and fever. The prognosis of local injuries depends on several factors including absorbed dose, type of radiation energy, and area/depth of tissue injury. Medical therapy is sufficient for injuries involving inflammation, moist desquamation, and ulceration, whereas dosimetry-guided surgical therapy is necessary for deep ulceration and necrosis.[167] Medical management of severe cases required hospitalization at specialized reconstructive surgery facilities. Newer cell and gene therapies for treating cutaneous syndrome include progenitor cells, adipose stromal cells, and stomal cells/mesenchymal stem cells.[507,508]

Erythema and Dry Desquamation

Radiation burns may progress from erythema to vesiculation, skin loss, and ultimately superficial or deep tissue necrosis that requires surgical intervention. The rule of nines applies to grading burn severity for thermal and radiation burns. The treatment of cutaneous radiation syndrome and thermal burn injuries is similar, except for the difficulty in demarcating the extent of a radiation injury. Mild, asymptomatic cutaneous erythema or dry desquamation requires no treatment other than softening the area with bland aqueous creams and avoiding tight clothing; moderate-to-severe erythema may require the addition of a low-dose, topical steroid cream. In general, inflammation and moist desquamation are treated medically, whereas deep ulcerations and necrosis require surgical treatment.[167]

Moist Desquamation

The presence of moist desquamation indicates the need to treat the burn as a wound. Contaminated burns are treated like thermal burns, except that more frequent dressing changes may be necessary in the first few days to limit the spread of contamination from the scab. Gentle rinsing of the burn wound is usually the most appropriate decontamination measure. Treatment of moist desquamation without infection or exudates involves the local application of topical antibiotic agents that do not retard epithelialization (e.g., Silvadene®, Neosporin®). Topical Bactroban® possesses limited gram-negative coverage; therefore, Bactroban® should be used with other antibiotics if a mixed infection is suspected.[509] Waterproof, occlusive dressings improve the resurfacing of the noninfectious, exudative wounds when applied in the first 6–24 hours postexposure and left in place for 24 hours including polyurethane films (Opsite®, Bioclusive®) and hydrocolloids (DuoDerm®, J & J Ulcer Dressing®).[510] Aquacel® dries the exudate by producing a gel effect. Although these materials vary in composition, they all provide a bacterial barrier. The choice of material depends on the wound's characteristics and requirements. Hydrocolloid dressings are effective for the management of radiation-induced moist skin desquamation and preventing *Pseudomonas* infections by lowering the pH,[511] whereas adhesive dressings (e.g., polyurethane films) should be used only when normal skin surrounds the wound. Vigorous cleansing and scrubbing of the burn wound should be avoided because of the potential for absorption of contamination across the damaged epithelial barrier. Contamination from insoluble radionuclides will slough with the eschar; therefore, the dressings and bed linen may become contaminated.

Deep/Full-Thickness Injury

Treatment of radiation-induced ulcers involves the administration of tetrachlorodecaoxide, hydrocolloid dressings, topical thrombocytic growth factors, and surgical intervention (i.e., aggressive debridement followed by rotation flaps or full-thickness skin graft) as needed. The timing and extent of surgical intervention depend on clinical judgment, the amount of underlying tissue damage, the presence of infection, and the persistence of pain. Determination of the extent of injury usually requires at least 24–30 hours after radiation exposure to accurately characterize the burn damage in conjunction with physical dosimetry. With the development of fixed erythema, demarcation of the burn wound appears; however, the extent of underlying damage cannot be accurately estimated from superficial changes.

Surgical intervention for life-threatening injuries in severely irradiated victims should be performed within 36–48 hours postexposure; elective procedures (closure of ostomies, reconstructive and cosmetic procedures) should be postponed for at least 45–60 days after recovery from radiation-induced immunosuppression. For a patient exposed to whole-body radiation doses of >2–4 Gy and likely to develop immunosuppression, early excision of burns and wounds, preferably with skin grafting, decreases infection risks.

Prophylactic antibiotics should be administered before surgery.[445] Intractable pain from deep radiation-induced lesions is especially difficult to control, usually suggesting the presence of the acute phases of vasculitis.[167] Over-pressurized devices with transparent walls and invaginated gloves increase the comfort of the patient and staff.

Beta particles penetrate skin in relation to their energy at the rate of ~0.5 cm/MeV. At surgery, the extent of the excision will depend on the isodose curves and the appearance of the tissue borders. Clinical experience at Goiania suggests blood pool imaging with ^{99m}Tc RBC may help determine the extent of cutaneous damage.[512] MRI studies of thick muscular structures help delineate the depth and extent of necrotic tissue. Surgical success requires removal of all necrotic and infected tissue to the level of good vascularity along with good soft tissue coverage for all underlying structures. In contrast to thermal burns, radiation burns require long-term surgical care rather than early excision and skin grafting. These patients require lifelong follow-up to monitor progression of fibrosis-induced ischemia and emergence of cutaneous malignancies. Experimental therapies for the reduction of radiation-induced cutaneous fibrosis include topical superoxide dismutase, pentoxifylline/α-tocopherol, and proteinase inhibitors.

Hospital Protocols and Drills

Management of radiation incidents involves: 1) preparation, 2) crisis management, and 3) long-term treatment of radiation-induced complications. The preparation phase includes emergency planning, assessment and procurement of equipment, assignment of control and command, identification of organizational responsibility, and delineation of important protective actions. Training emergency personnel involves background information on radiation, risk levels, protection methods, and management priorities. Because radiation accidents are rare, written protocols and annual drills are necessary to optimize the treatment of the radiation victim. These hospital plans should assume the need to treat at least one to five contaminated victims and triage a substantial number of walk-in patients for the presence of contamination. Resources for radiation protocols containing written procedures for radiation accidents, personnel job descriptions, medical equipment lists, and decontamination methods include books[438,442] and websites (https://orise.orau.gov/reacts/index.html, https://remm.hhs.gov/). Practice drills should be as realistic as possible, with a critique to improve performance following the drill. Videotapes are instructive, especially for the orientation of new personnel in the emergency department.

The protocol should designate a Radiation Emergency Area (REA) to receive contaminated victims and prevent the spread of contamination to other hospital areas. The control procedures for this area are similar to those for patients in strict isolation with buffer zones, clean areas, and contaminated rooms. A "floating" nurse and an aide should monitor the buffer area to ensure conformity to contamination protocols.

Figure 39.14 displays a common design for the REA. Ideally, the REA should be outside the main traffic flow of the hospital; however, this area should have direct access to the outside for the transfer of contaminated patients from the ambulance to the REA. The REA is not usually a dedicated area; therefore, advance communication is necessary to prepare the room prior to the ambulance's arrival. For critically injured patients, this preparation can be performed concurrently with treatment including nonslip floor covers (e.g., Herculite®, barbecue cloth), removal of nonessential equipment, and designation of contaminated areas with tape and rope.

Resuscitation equipment and supplies should be packaged in mobile containers for easy transfer to the REA. These supplies include decontamination supplies, long pairs of forceps for removal of radioactive metallic fragments, protective clothing, dosimeters, Geiger counters, and material for designating appropriate areas and collection of specimens. Protective clothing usually consists of water-resistant gowns, caps, plastic shoe covers, and surgical gloves. This clothing protects the individual only from α-particles, functioning more as a reminder to avoid contamination than protection against β- and γ-radiation. Reducing the time spent close to the radiation source and increasing the distance between medical personnel and the radiation source are more effective means of decreasing radiation exposure than shielding with lead or other materials.[514] The presence of radioactive metallic fragments in the patient, requiring careful placement in a lead-lined container, is an exception to this rule. Security is necessary to prevent unauthorized access; the medical staff should adopt universal precautions.

The REA should contain a shower, hot and cold water, telephone, resuscitation equipment, floor drains, and easily washable walls. Installation of elaborate drainage systems or sophisticated ventilation systems is probably not necessary to limit the spread of contamination to other areas of the hospital or the public.[513] Although filtering or separating airflow from the rest of the hospital is desirable, the relatively large size of most contaminated particles limits the spread of most contamination through the ventilation system. Similarly, the use of holding tanks for the discharge of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 39.14. Common design for radiation emergency area (REA). (Adapted from AMA).[513]

contaminated water is advantageous; however, the radiation hazard to the public is minimized by the relatively small and limited discharge of radioactive waste compared with the large volume of effluent from the hospital and community. The protocols for decontamination must follow all state and federal regulations for the discharge of radioactive effluent.

Specialty referral centers are available on a 24-hour basis to receive, survey, and treat radiation accident victims. In addition, some of these centers provide information on planning, training on the current methods of treating radiation victims, and population monitoring. Examples of these centers include the US Radiation Emergency Assistance Center and Training Site (REAC/TS) located at Oak Ridge Hospital of the Methodist Church in Oak Ridge, Tennessee (emergency number: 865-576-3131), Centers for Disease Control (CDC) Radiation Studies Branch: https://emergency.cdc.gov/radiation/pdf/population-monitoring-guide.pdf, International Atomic Energy Agency Emergency Preparedness and Response Section: http://www-pub.iaea.org/MTCD/publications/PDF/EPR-MEDICAL-2005_web.pdf, and the World Health Organization (WHO) Radiation Emergency Medical Preparedness and Assistance Network (REMPAN Directory): (https://www.who.int/groups/rempan).

Chapter 40

IONIZING MEDICAL IMAGING AND RADIOTHERAPY

Ionizing radiation contains sufficient energy to remove tightly bound electrons from their orbits and create ions including both particulates (α- and β-particles) and electromagnetic energy (γ-rays, X-rays). Health concerns regarding the use of ionizing medical radiation (i.e., conventional X-rays, CT scanning, radiotherapy, radionuclides) include primarily teratogenesis and carcinogenesis. The measure of potential radiation exposure from diagnostic medical equipment in SI units is the gray (Gy) or milligray (mGy); the radiation absorbed dose (rad) is the analogous, less commonly used, conventional unit (1 rad = 0.01 Gy). The equivalent dose is the calculated radiation dose after adjusting for different radiation types and tissue densities with the radiation weighting factor (W_R), assuming the body is homogeneous. The sievert (Sv) is the SI unit for the equivalent dose; the rem is the conventional unit. For X-ray, the γ- and β-radiation W_R is 1; therefore, 1 Gy = 1 Sv for these types of radiation. Multiplying the radiation dose equivalent by a tissue-weighting factor (W_T) to account for the radiosensitivity of different tissues and summing the doses for all the organs produces the effective radiation dose. Within the last two decades, the average effective radiation dose from medical imaging has increased substantially; medical imaging contributes almost 50% of the overall average radiation dose to the US population compared with 15% in 1980.[1]

DIAGNOSTIC RADIATION

HISTORY

Over the last 50 years, technical improvements in conventional radiography significantly reduced the radiation dose for patients and staff as image quality improved.[2] During this time, film-screen radiography transitioned from hand-dipped film processing to modern electronic image receptors (photo-simulated phosphors in computed radiography, CsI needle phosphors in indirect-conversion digital radiography flat panels, amorphous selenium photoconductors in direct-conversion digital radiography flat panels).[3] Most radiographical imaging during the 1950s involved single-phase X-ray generators that had 100% ripple in the high voltage waveforms and relatively low energy X-rays; consequently, the patient received relatively high radiation doses despite less penetrating X-rays. The first automated film processors were distributed in 1957. Three-phase equipment and then high-frequency units replaced single-phase X-ray generators, resulting in minimal high-voltage ripple and shorter X-ray exposure time.[4] Along with the implementation of quality

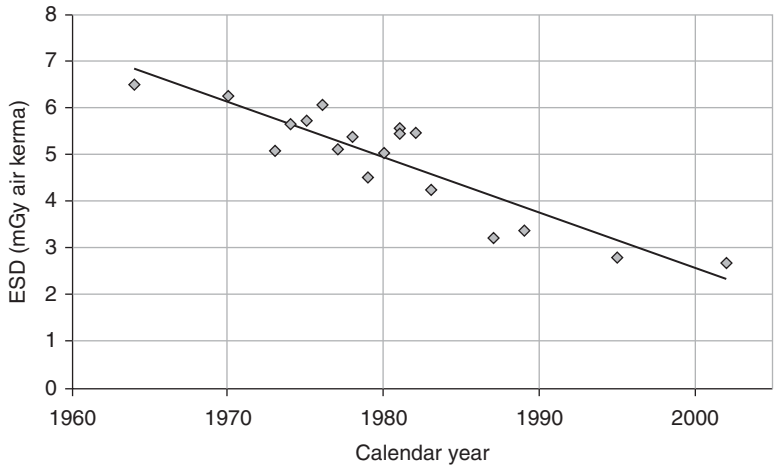

FIGURE 40.1. Estimated average surface radiation exposure (entrance surface dose, ESD) of US adults from AP abdominal X-ray as measured by the entrance radiation doses 1960–2005. (Redrawn from Huda et al.).[2]

control programs, several advancements substantially reduced the radiation dose to patients over the next 50 years, including rare earth X-ray beam filters (erbium, niobium) and fast rare earth film-screen systems. Based on historical estimates, the entrance skin radiation doses for chest X-ray examinations decreased from 68 mGy in 1902 to 0.13 mGy more recently.[5] Similarly, the radiation dose for a conventional abdominal X-ray decreased from 189 mGy in 1902 to 2.73 mGy currently. Figure 40.1 demonstrates the decrease in entrance (surface) radiation exposure from 1960–2005 for an AP abdominal X-ray in US adults; similar declines occurred for the entrance radiation dose for PA chest and AP lumbosacral spine radiographs.

In the early 1970s, the introduction of computerized tomography (CT) revolutionized diagnostic radiology by providing three-dimensional views of specific organs and body regions of interest. The use of axial and helical (spiral) CT increased rapidly with >80 million scans performed by the late 2000s.[6] Although the cancer risk is small, the CT increases the radiation dose/examination; and the overall cancer risk as CT usage dramatically increased in the 2010s and 2020s. The dose from a conventional abdominal X-ray series (three radiographs) is ~15 times smaller than the stomach receives from an abdominal CT scan.

EXPOSURE

Exposure describes the radiation intensity in the field surrounding the patient rather than the amount of interaction between the radiation and the tissue. The entrance surface dose (older term, entrance skin exposure or ESE), is a measure of the amount of radiation at the presumed skin location where the beam enters; the ESD can be calculated from the kVp and the filtration parameters of the X-ray machine.[7] Therefore, the skin dose is the maximum dose received by any portion of the body. The radiation dose equivalent (Sv) is the product of the absorbed dose (Gy) and a dimensionless weighting factor. Multiplying the organ equivalent dose by the tissue weighting factor to account for tissue radiosensitivity and summing the organ dose produces the whole-body effective radiation dose (effective dose). The value of the effective dose changes with time as various factors are adjusted, usually to reduce the radiation exposure to a level as low as reasonably achievable. Figure 40.2 displays the relationship between the absorbed dose, dose equivalent, and whole-body effective dose.

The whole-body effective radiation dose reflects radiation risk at the population level rather than the individual level; the latter depends on patient-specific factors (e.g., age, life expectancy, medical conditions,

TABLE 40.1. Estimated range of radiation doses from a variety of diagnostic X-ray procedures. (Adapted from National Research Council BEIR VII Committee).[9]

Procedure	Examination Type	Radiation Doses
Plain conventional X-rays	Chest, bones, skull, abdomen	0.02–10 mGy
Complex conventional X-rays	Gastrointestinal series, barium enema, intravenous urogram	3–10 mGy
Computed tomography (CT)	Head, abdomen-pelvis, whole-body	5–15 mGy
Spiral CT	Head, whole-body	10–20 mGy
Angiography	Coronary, aortic, peripheral, carotid, abdominal	10–200 mGy
Interventional procedures	Angioplasties with stent, percutaneous dilatations, closures, biopsy procedures	10–300 mGy

body habitus). The use of the effective radiation dose allows a comparison of typical radiation doses of various imaging technologies or procedures (e.g., barium enema vs. CT abdomen) in different hospitals or countries, assuming the patient populations are similar; thus, the effective radiation dose is a quality-control tool that can identify deviations from standard practices of a specific imaging examination. Table 40.1 lists the approximate ranges of radiation doses from several types of diagnostic X-ray procedures.

Since the 1980s, effective radiation doses from common radiographic procedures and CT examinations for adults have trended downward along with the estimated radiation dose per procedure.[10] However, the frequency of relatively high-dose diagnostic examinations has increased. These procedures include some computed tomography (chest, abdomen/pelvis), nuclear medicine (heart – ^{201}Tl chloride, tumors – PET ^{18}F-fluorodeoxyglucose, bone – ^{99m}Tc phosphate), and fluoroscopically guided (cardiac angiography, barium enema) examinations. Fetal radiation doses from maternal medical irradiation vary several 1,000-fold depending on the specific procedure.[11] High fetal radiation doses from maternal diagnostic procedures involve the use of certain radiographical imaging (AP lumbar spine, AP pelvis, AP abdomen), diagnostic (barium enema, intravenous pyelogram, AP urinary bladder), computed tomographic (pelvis, liver, lumbar spine), and nuclear medicine (^{67}Ga citrate, heart – ^{99m}Tc methoxyisobutylisonitrile, kidney – ^{99m}Tc mertiatide) examinations. Although the estimated entrance surface dose for radiographical examinations and the dose-area product for fluoroscopic procedures increase with age, the overall radiation dose is higher in pediatric patients than adult patients because the larger adult body size attenuates a relatively greater amount of the primary X-ray beam.

Radiography

An X-ray generator is a regulated high-voltage DC power supply typically with the following operating range: power (i.e., 10–200 kW); output voltage (i.e., 20–160 kV); and current (10–5,000 mA).[4] Sealed vacuum X-ray tubes produce high-speed electrons that strike a metal target and release heat and high-energy photons (X-rays). Lead containers (housing) surround the X-ray tubes to focus the X-rays through ports or windows into a useful beam. Diagnostic X-ray tubes are shielded to minimize the leakage of radiation (i.e., <1 mSv/hour at 1 m from the focus). An aperture or collimator (i.e., a device to reduce the cross-sectional area of the photon/electron beam) defines the primary field limits. A filter absorbs the low-energy photons that do not contribute to the resolution of the X-ray picture to limit patient exposure to low-energy photons in the primary beam. High frequency units replaced the single-phase X-ray generators. The advantages of the newer units include the delivery of higher and more reliable energy X-ray spectra for identical kVp settings and the reduction in the size of the high-voltage circuits.

Planar Radiographs

The complex interaction of a variety of factors determines the clarity of a radiograph including subject contrast, sharpness, resolution, radiographical mottle, fog/scatter, and radiographical contrast; these factors depend on machine parameters (voltage, amperage, grid selection, image receptors).[12] Modern electronic image receptors (e.g., photo-simulated phosphors for computed radiography, CsI needle phosphors coupled to solid-state light detectors for digital radiography) and fast rare earth film-screen systems replaced the older hand-dipping techniques.

Kerma is the sum of the initial kinetic energies of all charged particles liberated by uncharged particles (e.g., X-rays, neutrons); hence, kerma is a measure of the kinetic energy released per unit mass. The kerma-area

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

product (KAP) measures the total X-ray beam intensity by multiplying the average air kerma (energy in X-ray beam per unit mass of air in small, irradiated air volume measured in Gy) by the area of the X-ray beam (cm^2) expressed as Gy-cm^2 in Equation 40.1. The KAP does not change with distance from the X-ray tube.

$$\text{Kerma-Area Product (KAP)} = \text{average air kerma (Gy)} \times \text{X-ray beam cross-sectional area } (cm^2) \quad \text{(Equation 40.1)}$$

The KAP (also known as dose-area product, DAP) provides a good estimate of the total amount of radiation delivered to the patient during a radiographical examination; the use of KAP allows the comparison of radiation exposure between various institutions and recommended values (e.g., diagnostic reference level).[13] However, KAP is not a surrogate for the effective radiation dose.[14] After accounting for X-ray beam quality, KAP (Gy-cm^2) reflects the energy incident on a patient in any area of radiological imaging; conversion of the KAP to the effective radiation dose and estimated organ doses requires adjustment for beam quality (projection, parameter settings), the patient's physical characteristics (size/age), body region, and projection of the X-ray beam.[15] Converting the KAP to conceptus dose also depends on gestational age and the closeness of the conceptus to the primary beam. Estimation of organ doses requires direct measurement in anthropomorphic phantoms or the use of Monte Carlo computational software; these values vary depending on the software and phantom design. In a study of conventional planar X-ray examinations comparing direct measurement of uterine doses in a phantom and calculated uterine doses from two software programs (WinODS,[16] PCXMC[17]), the factors for converting KAP (Gy-cm^2) to uterine radiation doses (mGy) ranged from 0.01 mGy/Gy-cm^2 (chest 2-view, fetus <3 months) to 3.8 mGy/Gy-cm^2 (L5 single frontal view, fetus 9 months).[18]

The nominal (benchmark) KAP value for radiographs is ~1 Gy-cm^2 compared with 20 Gy-cm^2 for fluoroscopy and 100–300 Gy-cm^2 for interventional radiography.[14] KAP values for common plain films range from 0.1 Gy-cm^2 (posteroanterior chest view) to 2.5 Gy-cm^2 (anteroposterior abdomen or pelvis), as displayed in Table 40.2.

Radiation exposure is typically higher for radiographs of the spine and abdomen than the chest and extremities. X-rays are not produced unless the X-ray machine is turned on; therefore, no residual X-rays remain in the room after the X-ray machine is switched off. The patient does not become radioactive after X-ray examination.

TABLE 40.2. Representative kerma-area product (KAP) values for common planar radiographs in normal-sized adults. (Data from Huda).[14]

Examination/Projection	Image Number	KAP (Gy-cm^2)
Skull – lateral	1	0.5
Skull – anteroposterior (AP)/lateral	2	1.5
Chest – posteroanterior (PA)	1	0.1
Chest – posteroanterior/lateral	2	0.3
Abdomen or pelvis – anteroposterior (AP)	1	2.5

Mammography

Mammography requires relatively high radiation exposure to achieve the resolution required for good radiographic images. In the 1960s, industrial film-based techniques delivered radiation doses up to 150 mGy/procedure. In the 1970s and early 1980s, selenium detector-based imaging (xerography) gained wide acceptance in mammography; this technique involves the use of tungsten X-ray tube operated at 40–50 kVp with an aluminum filter and a xerographic image receptor; however, by the late 1980s, screen-film imaging became the dominant technique in mammography.[19] This latter method uses a molybdenum or rhodium filter and an intensifying screen-film combination as the image receptor. The radiation dose to the glandular tissue in the breast as measured in normalized glandular dose coefficients is an important determinant of stochastic effects. Computer-based methods employing Monte Carlo techniques now are the principal tool for optimizing the X-ray spectrum for digital mammography.[2]

Fluoroscopy

The introduction of image intensifiers in the 1950s provided a much brighter screen image than older fluoroscopy screens that required a dark room for viewing and delivered large radiation doses to the patient. However, radiation levels (air kerma) remain relatively high (i.e., up to 87 mGy/minute) including scattered X-ray radiation to the staff.[12,20] Because of image quality requirements, even fluoroscopy that uses spot films with radiographical cassettes produces substantial radiation doses. Factors affecting variations in the amount of radiation exposure during fluoroscopy include screening time, number of films, the resolution of the TV or film image, and the area of imaging.[21] Technological improvements over the last 50 years have reduced radiation doses to patients and staff, including

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

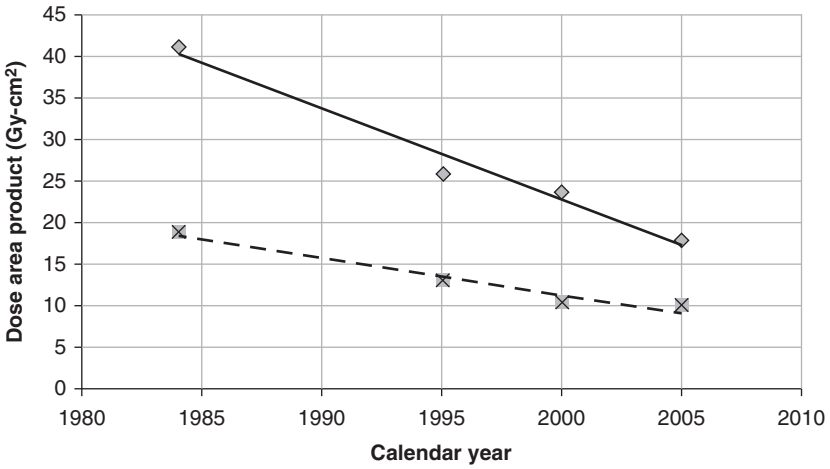

FIGURE 40.3. Mean dose area product (DAP) for UK fluoroscopy procedures (Gy-cm^2) from 1980–2005. DAP meters measure the radiation dose in air (i.e., entrance dose) over a specified area, typically Gy-cm^2; these devices are ionization chambers that cover an area larger than the X-ray beam. The upper line of diamond symbols represents barium enema examinations, whereas the lower line of "×" symbols represents barium meals. (Huda et al.).[2]

the introduction of large fields-of-view intensifiers with automatic dose control, pulsed fluoroscopy, last frame hold, and cumulative fluoroscopy times to minimize the dose area product.[22,23] Figure 40.3 demonstrates the ~50% reduction in radiation exposure from fluoroscopic examinations of the gastrointestinal tract (barium meals, barium enema) from 1980–2005 as measured by the mean dose area product (i.e., entrance dose delivered over an area, Gy-cm^2).

Using kerma-area-product (KAP) values as a measure of average X-ray beam intensity, radiation exposure during fluoroscopic examinations of the urological (cystogram, voiding cystourethrogram) and gastrointestinal (esophagram, upper GI, small bowel follow-through, barium enema) tracts is ~20 Gy-cm^2. Figure 40.4 displays KAP values for common gastrointestinal and urological studies at the Medical College of South Carolina.

Angiography

Angiography is a modified fluoroscopic procedure that requires the placement of catheters under fluoroscopic control. The amount of radiation absorbed by the patient is in the upper range of diagnostic tests because of the use of fluoroscopic placement and the utilization of large numbers of radiographs to demonstrate anatomy. The introduction of digital subtraction angiography and dose-saving features (last frame hold, shaped filters rotating and iris collimators, dose area product meters) reduced radiation exposure to patients and staff. The collimation of the X-ray beam to the specific area of interest (e.g., heart) reduces the exposure of the patient's other organs. The injection of the contrast media by pump during coronary angiography can significantly reduce the radiation exposure of the operator.

Interventional Radiology

Interventional radiology involves a wide range of procedures and potential for overexposure including embolization procedures, shunt creation, joint replacement, central venous catheter placement, hepatic/biliary and sclerotherapy interventions, and renal/visceral artery stent placement. There is large variation in radiation exposures between institutions. Pediatric interventional radiology exposure is particularly susceptible to overexposure because of the wide range of children's sizes, the complexity of the procedure, its duration, and the necessity to stand closer to the beam. In a study of 2,142 interventional radiology procedures at 12 fluoroscopic units in 7 US academic institutions, mean KAP for the 35 types of interventions was ~200 Gy-cm^2 with a range of mean values from 26 Gy-cm^2 (nephrostomy obstruction) to 560 Gy-cm^2 (arteriovenous malformation embolization spine).[24] The mean KAP value for 177 arteriovenous malformation embolizations in the head was 340 Gy-cm^2 (range, 4–1,350 Gy-cm^2). Nominal conversion factors can estimate the approximate effective radiation dose from KAP for radiographical and fluoroscopic (*but not CT*) procedures; however, using this conversion value and DAP (also known as KAP) does not substitute for the

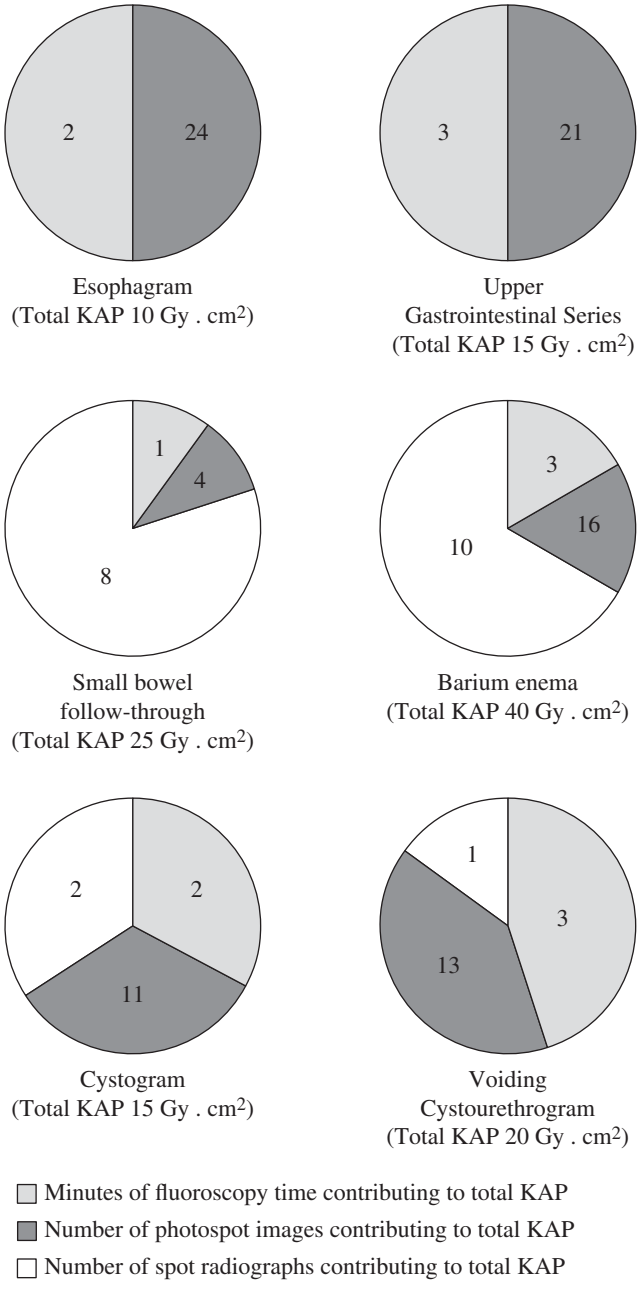

FIGURE 40.4. Percentage of total kerma-area-product (KAP) attributed to fluoroscopy time, photospot images, and spot radiographs during fluoroscopically-guided imaging of common gastrointestinal and urologic studies in normal-sized adults at the Medical College of South Carolina. The numbers within the circles represent the following: fluoroscopy time in minutes (shaded portion), total photospot images (dark portion), and total spot radiographs (clear portion). (Data from Huda).[14]

TABLE 40.3. Representative values for converting KAP to effective radiation dose for radiographic and fluoroscopic procedures on normal-sized adults. (Huda)[14]

Exposed Region – Projection	Conversion Factor (Effective Dose/KAP) (mSv/Gy-cm^2)
Head	0.03
Body – anteroposterior	0.25
Body – posteroanterior	0.15
Body – lateral	0.1

calculation of the effective dose. Table 40.3 displays representative conversion factors for normal-sized adults; these values do not apply to children or adults without normal-sized bodies.

Computed Tomography

Computed tomography (CT) links mechanically rotating detectors with the mathematical reconstruction of an image formed by a large number of small X-ray beams.[25] The scanning portion of CT incorporates an X-ray tube that includes a collimator to confine the X-ray beam to thin sections with an opposing detector that surrounds the patient. The X-ray tube irradiates a thin slice (1–10 mm) of tissue as it progresses around the patient. The distribution of energies in the polychromatic beam of X-ray photons ranges from 30–140 keV with the incident beam possessing a half-value layer up to 10–12 mm aluminum (80 keV effective energy).[26] In the 1970s, single detector CT scanners first appeared. The images were acquired in the axial plane as individual slices 8–13 mm thick; by 1975, reconstruction techniques using axial CT data allowed the construction of coronal and sagittal images. In the 1980s, 4-channel multidetector computed tomography (MDCT) scanners were introduced for commercial use. Since that time, improvements in CT scanner mechanics have resulted in faster X-ray gantry rotation and z-axis (cephalocaudal) movement, thinner collimation, and the development of electrocardiographic (ECG) gating.[27] Spatial resolution is the ability to discern two objects as separate, whereas temporal resolution is the length of time necessary to image an object. Seventh-generation 64–320 channel MDCT scanners now offer increased spatial and temporal resolution with gantry rotation times of 0.25 seconds and collimation as low as 0.24 mm. Cardiac studies account for a large majority of the collective radiation dose from nuclear medicine procedures. Electrocardiographic gating allows the acquisition of image data and image reconstruction at a specific time during the R–R

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

interval. In prospective gating, the radiation source is active only during part (i.e., ~70–80%) of every other cardiac cycle; thus, the radiation dose is reduced. Using the kerma area product (KAP), typical KAP values for head CT are ~13 Gy-cm^2 and ~25 Gy-cm^2 for a body scan compared with ~1 Gy-cm^2 for head/chest radiographs, ~5 Gy-cm^2 for abdominal radiographs, and ~100 Gy-cm^2 for interventional procedures involving fluoroscopy.[28]

DOSE EFFECT

Absorbed dose is the measure of the amount of energy absorbed per unit of mass (i.e., tissue) within the radiation field measured in gray (Gy). The actual dose received by specific organs (i.e., organ dose) is the best measure of risk; calculation of this value is complex because the diagnostic beam exposes only a portion of the body; additionally, the tissues within the body attenuate the beam. The average *whole-body effective dose* measured in sievert (Sv) allows the standardization of the different risks of irradiating different organs by summing the organ dose equivalents and adjusting for tissue radiosensitivity (tissue weighting factors). Therefore, this measure permits a comparison of the estimated radiation dose between individuals. The effective dose approximates the true risk; however, substantial variation in individual doses occurs because of patient-specific factors (age, health, sex, habitus) and the difficulty estimating true radiation doses.

Adults

Figure 40.5 compares the estimated US annual per-capita effective radiation dose from various sources in 1980 (3.0 mSv) and 2006 (5.6 mSv).[29] The recent increase in medical radiation results primarily from the increased use of CT scanning, particularly in patients receiving relatively high annual radiation doses (>20 mSv).[1] In a retrospective analysis of medical records from 1996–2010 from six large integrated US health maintenance systems (1–2 million member-patients/year), the mean per capita effective dose increased from 1.2 mSv in 1996 to 2.3 mSv in 2010.[30] By 2010, 3.9% of the enrollees received annual radiation exposure exceeding 50 mSv (i.e., the US occupational limit). The utilization rates for radiography and angiography/fluoroscopy remained relatively stable during this 15-year period. Figure 40.6 displays the average contribution of various *artificial* radiation sources, including medical imaging procedures, to the overall annual US per-capita whole-body effective radiation dose during the mid-2000s; this estimate excludes natural radiation (e.g., radon, terrestrial, cosmic).

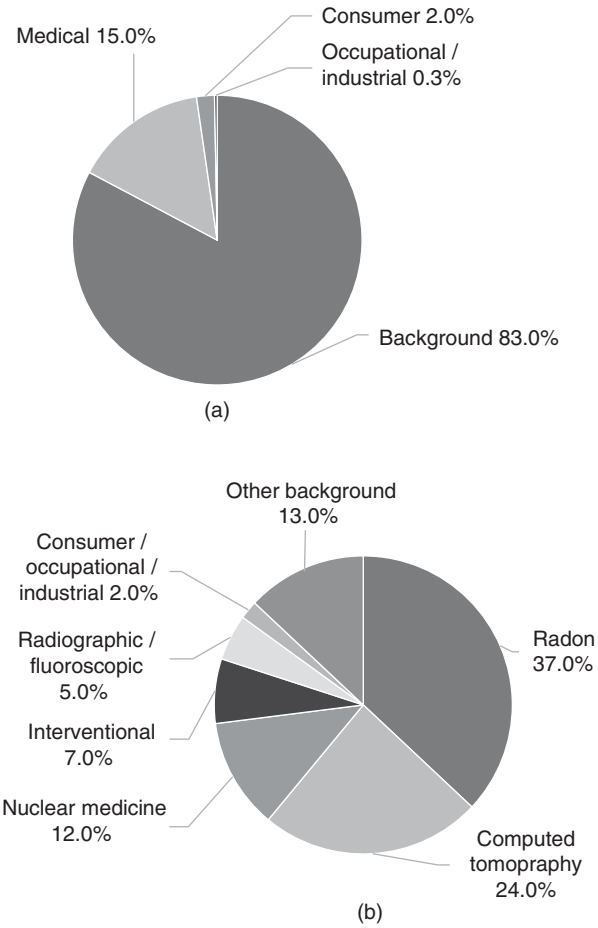

FIGURE 40.5. Annual US per-capita effective radiation dose from various sources for (a) 1980 and (b) 2006, demonstrating the increasing contribution of medical imaging to the annual effective radiation dose. (Modified from Hendee et al.).[29]

Table 40.4 displays average effective radiation doses (mSv) comparing the radiation doses of common diagnostic imaging procedures. The effective dose is a measure of the distribution of radiation in an organ when the distribution is not homogeneous (e.g., CT scans). This value multiplies the organ dose by a weighting factor specific to the anatomy of the organ scanned.

Although the radiation dose equivalent allows comparisons of different medical imaging examinations, the organ dose provides a better estimation of true risk. Organ doses are usually calculated from computer models or measured in anthropomorphic phantoms; changes in CT scanner design and operator characteristics cause variability in the results from these two methods.[31] A study of third-generation CT scanners during the early 1990s used thermoluminescent dosimeters to measure

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 40.6. Annual US per-capita effective radiation dose from artificial (human) sources in 2006. Diagnostic radiography/fluoroscopy represents the portion of the effective radiation dose attributed to conventional (planar) X-rays and fluoroscopy. (Modified from Mettler et al.).[1]

TABLE 40.4. Typical effective radiation dose for common diagnostic imaging procedures using typical machine settings. The effective radiation dose allows a rough comparison between different CT and conventional radiographs, but these values are less accurate estimates of risk than the organ dose. The actual dose differs among individuals and institutions. (Adapted from Bardo et al.).[27]

Procedure	Effective Radiation Dose (mSv)
Chest X-ray	0.02
Mammogram	0.13
Brain CT	1–2
Chest CT	5–7
Coronary artery angiography (CCA)[a]	2–10
Coronary artery angiography – retrospective ECG-gating, 64 channel	10–15
Coronary artery angiography – prospective ECG-gating dose modulation (80 kV)	2–4
Coronary artery calcium electron beam CT	0.6
Coronary artery calcium CT – MDCT prospective ECG-gating	1–3
Rubidium PET stress test	4.9
Sestamibi SPECT nuclear stress test	12–23

[a] The estimated annual radiation dose of conventional CT coronary artery angiography: cardiologist, 0.1–5 mSv; nurse, 0.01–0.5 mSv.

free-in-air air kerma at the rotation axis of the CT gantry and anthropomorphic phantoms to simulate radiation exposure. The estimated mean organ doses for CT examinations of the trunk were the following: skin, 22–36 mGy; lungs, <1–18 mGy; kidneys, 7–24 mGy; and ovaries, <1–19 mGy.[32] Subsequently, newer techniques reduced the organ doses from CT scans. Table 40.5 compares the typical organ dose from several types of CT examinations using typical machine settings during the mid-2000s. The actual organ dose of an individual receiving a CT depends on multiple variables including patient size, operator characteristics, scanning parameters, and the type of scanner.

TABLE 40.5. Comparison of typical organ radiation doses for several radiological studies using common machine settings. The actual dose received by an individual depends on the scanner, operator characteristics, and study parameters. (Adapted from Brenner and Hall).[6]

Procedure	Organ	Organ Dose (mSv/mGy)[a]
Dental X-rays	Brain	0.005
Posterior-anterior Chest X-ray	Lung	0.01
Lateral chest X-ray	Lung	0.15
Screening mammography	Breast	3
Chest CT	Breast	21.4
Coronary angiography CT	Breast	51
Abdominal X-ray	Stomach	0.5
Barium enema	Colon	15
Abdominal CT (adult)	Stomach	10
Abdominal CT (adult)	Colon	4
Abdominal CT (neonate)	Stomach	20

[a] For X-ray radiation including CT scans, 1 mGy = 1 mSv. The organ dose is a more accurate measure of risk than the effective dose.

Conventional X-Rays

The radiation dose received by a patient from an X-ray machine is a complex summation of the number of projections, technical factors, anatomy, and position of the patient. Technical factors include proper collimation and filtration, orientation of the beam, leakage radiation, appropriate shielding, and machine parameters. Doses are concentration units (energy/unit mass) that do not allow the simple addition of doses following irradiation of different parts of the body.

The primary concern with radiation from medical imaging is its *potential* to increase cancer risks. Table 40.6 lists the equivalent number of chest X-rays and the equivalent length of exposure to cosmic radiation to accumulate the same effective radiation dose as absorbed during common radiographic procedures.

In children, conventional X-rays of the limbs, chest, and teeth account for ~70% of all X-ray examinations while contributing <2% of the overall population radiation dose.[33] The gonads of patients irradiated with plain X-rays receive small amounts of radiation (<10 μGy) when the X-ray beam is directed outside the abdominal area, including X-ray examinations of the chest, cervicothoracic spine, head, and upper extremities.

TABLE 40.6. Relative comparison of typical estimated effective dose (effective dose equivalents) of various medical imaging examinations with: 1) the number of single conventional PA chest X-rays required to accumulate an equivalent radiation dose; and 2) the number of daily exposures to cosmic radiation necessary to accumulate the same radiation dose (assuming an annual cosmic radiation dose of 2.4 mSv). Some variability exists in the estimated effective radiation dose for radiographical examinations between this table, Table 40.4, and other sources in the medical literature because of differences in assumptions about the techniques. (Mazrani et al.).[33]

Examination	Typical Effective Dose (mSv)	Equivalent Chest X-rays (number)	Equivalent Length of Cosmic Radiation (days)
Skull X-ray	0.7	3.5	11
CT head	2.3	115	365
PET head scan (F-18 FDG)[a]	5	250	840
Thyroid scan[b]	1	50	183
Single PA chest X-ray	0.02	1	3
CT chest	8	400	1,314
Abdomen X-ray	1.0	50	183
Pelvis X-ray	0.7	35	122
CT abdomen or pelvis	10	500	1,643
Barium meal	3	150	488
Intravenous urogram	2.5	125	427
Kidney scan[b]	1	50	183
Hip X-ray	0.3	15	49
Lumber spine	1.3	65	213
Limb/joint X-rays[c]	<0.01	<0.5	<1.5
Bone scan[b]	4	200	657

[a] Fluorodeoxyglucose positron emission tomography (^{18}F-PET radionuclide) scan. [b] ^{99m}Technetium radionuclide study. [c] Except hip.

The estimated effective dose for lithotripsy depends on fluoroscopy time, the number of spot films, and the entrance skin doses (ESDs). The estimated effective dose in 125 patients undergoing lithotripsy using a Siemens Lithostar system was 0.75 mSv based on calculations from radiation exposure techniques (kVp, field size, number of exposures/projections) and phantom-based radiation dose measurements.[34] The estimated effective dose in the medical literature for lithotripsy varied up to 1.63 mSv in a study of 50 patients with mean fluoroscopy times of 204 seconds (range: 90–372 seconds), mean ESD for oblique projection of 76.5 mGy (range: 14–200 mGy), and mean ESD for PA projection of 44.5 mGy (range: 8–115 mGy).[35]

Computerized Tomography

CT scanning delivers substantially more radiation to the patient than conventional X-rays (e.g., PA chest, AP abdomen); the radiation exposure is usually substantially higher for single body CT scans than single head CT scans. The introduction of CT scanning has significantly impacted the per capita radiation dose from medical procedures, as displayed in Figure 40.5. Although computed tomography (CT) accounts for ~9% of all radiological examinations, the estimated portion of the total medical radiation dose for CT is ~47%.[33] By the early 2020s, CT usage increased over 30% compared with the late 2000s.

Effective Radiation Dose

The effective (radiation) dose reflects the dose and differences in the radiosensitivity of various organs and regions of the body; this value correlates to the risk of the uneven exposure delivered by a CT scan, calculated as an equivalent uniform whole-body dose.[36] Over the last several decades, the average effective radiation dose has decreased below 10 mSv with some cardiac and pediatric CT scans routinely delivering effective doses of <1 mSv.[37] The typical adult effective doses of a single head CT scan is ~1–2 mSv compared with 5–10 mSv for a single body CT scan (chest, abdomen/pelvis) and ~20 mSv (range, 12–31 mSv) for cardiac 64-detector CT angiography.[38,39] However, radiation doses for specific CT studies may vary >10-fold between institutions as a result of differences in scanner design and examination protocols.[40] The variation in dose reflected different types of CT examinations.

Newer radiation techniques account for some reductions in radiation doses from radiological procedures. In a study of the medical literature for reported and calculated effective radiation doses, the radiation from noncardiac (head, chest, abdominal) CT scans was significantly higher ($P < 0.05$) in 1991–1995 than

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 40.7. Reported median and range of effective radiation doses (mSv) for non-cardiac CT scans of adults in the Pantos et al. study of the medical literature, 1991–2009. (Data from Pantos et al.).[41]

in 1996–2009; the radiation doses after 1996–2009 remained statistically similar.[41] An analysis of low-dose CT radiation dose levels for 12,529 patients undergoing lung cancer screening CT scans at 72 institutions from 2016–2017 reported a median effective dose of 1 mSv (IQR: 0.7–1.4 mSv).[42] As noted in Figure 40.7, the range of effective doses received by adults during CT scanning varies widely between different institutions and commercial scanners; this variability results from differences in scanner design and examination protocols. Widespread clinical use of coronary CT angiography began in 2004 with the introduction of 64-slice multidetector scanners that delivered ~16 mSv (range, 9–21) without current modulation.[43] Since that time, new dose reduction protocols involving ECG-based tube current modulation, high-pitch spiral scanning, lower peak tube voltage, prospective or axial scanning, and iterative CT data reconstruction have reduced radiation doses from some scans to ≤1 mSv (high-pitch spiral scan).

Patient habitus affects the effective radiation dose. Obese patients typically receive greater radiation doses than patients with normal BMI from the increased dose necessary to reduce image noise and produce acceptable images. A study of 91 CT scans of the body compared the organ dose and $CTDI_{vol}$ (integrated radiation dose from acquiring a single scan divided by the total nominal scan width or beam collimation) received by patients weighing 60–100 kg when the radiation exposure was determined by the dose required to produce a constant level of image noise.[44] The organ dose to the liver varied 2-fold, whereas the $CTDI_{vol}$ varied 3-fold. Effective doses may exceed 100 mSv in extremely obese patients undergoing radiographical examination of their abdomen.[45]

CT coronary angiography is a noninvasive diagnostic modality to detect the presence of coronary atherosclerosis. The use of ECG-gating improves temporal resolution and minimizes imaging artifacts caused by cardiac motion while reducing the radiation dose by delivering the majority of the radiation dose during the passive filling of the ventricles (diastole).[46]

CT Dose Index (CTDI)

The CT dose index (CTDI, mGy) represents the average absorbed dose along the *z*-axis from a series of contiguous exposures calculated by dividing the integrated absorbed dose from one axial CT scan (i.e., one rotation of the X-ray tube) by the total beam width. The CTDI theoretically estimates the average absorbed radiation dose only in the irradiated volume independent of the scan length; however, the radiation dose in this volume varies slightly to moderately across the field of view. A weighted average of the CT dose index ($CTDI_w$) measured at the center and periphery of dose phantoms provides a convenient single number estimate of patient dose for a procedure; this value

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

accounts for the nonuniform radiation dose inside the irradiated tissue. The $CTDI_w$ or a related indicator, $CTDI_{vol}$, is usually displayed on the operator's console.[47] The $CTDI_{vol}$ spreads the dose corresponding to the $CTDI_w$ over a specified length of the z-axis. This value is the best measure of the average radiation dose at a point within the scan volume for a particular scan protocol.[8] The $CTDI_w$ is a convenient indicator of scanner radiation output for a specific tube current-exposure time product (mAs) and tube voltage (kVp). The $CTDI_w$ represents the average absorbed radiation dose over the x–y directions, whereas the $CTDI_{vol}$ represents the average absorbed radiation dose over the x–y–z directions with z direction parallel to the table feed. Figure 40.8 lists the estimated median and range of the $CTDI_w$ in a study of values for noncardiac CT scans reported in the medical literature from 1991–2009.

CT dose index (CTDI) is difficult to measure in the patient. Although the CTDI is a useful quality control measure, this measurement is only indirectly correlated to organ dose (i.e., the distribution of effective radiation dose in an organ) and cancer risks. Displayed $CTDI_{vol}$ (volume CT dose index) represents the radiation **dose** over a volume in a plastic phantom rather than the actual **dose** delivered to the patient; the latter value depends on the size of the patient among other variables.[48] These values allow users to compare estimated radiation doses for each CT examination. In a study of 636 patients by the International Atomic Energy Agency, the average ($CTDI_{vol}$) was 39 mGy for head CT scan compared with 9.3 mGy for chest CT scan and 10.4 mGy for abdominal CT scan.[49] In a study of 199,656 consecutive CT examinations in 83,181 adults and 3,871 consecutive CT examinations in 2,609 children at 5 of the University of California medical centers during 2013, the average values for children were ~50% of adult head CT scans and ~25% of adult body CT scans.[50] Figure 40.9 compares the median and interquartile ranges for $CTDI_{vol}$, dose length product, and effective doses for adults during common CT scans at these institutions.

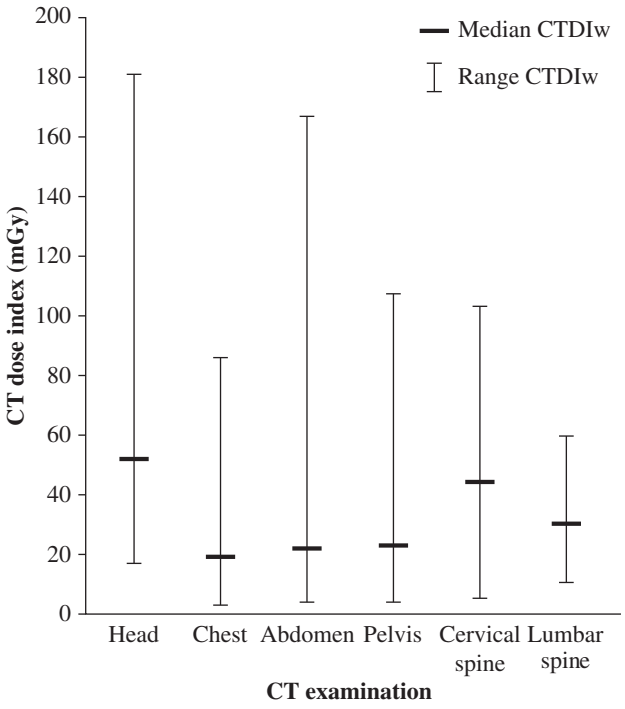

FIGURE 40.8. Reported median and range of CT dose index ($CTDI_w$, mGy) for non-cardiac CT scans of adults in the Pantos et al. study of the medical literature, 1991–2009. (Data from Pantos et al.).[41]

Size-specific dose estimates (SSDEs) are available on the American Association of Physicists in Medicine website (https://www.aapm.org/pubs/reports/rpt_204.pdf), where the report provides correction factors for the $CTDI_{vol}$ values for CT body scans for the entire range of patients (newborns to adults).[51] The SSDE is the correction factor multiplied by the $CTDI_{vol}$. This value is an estimate of the radiation dose in the soft tissues of the irradiated scan volume within ~20% when the CTDI phantom used for the displayed $CTDI_{vol}$ is known.[51]

Dose Length Product (DLP)

The displayed $CTDI_{vol}$ (volume CT dose index) on the CT scanner is an estimate of the average radiation dose in the cross-sectional area of the cylinder in a phantom rather than a direct measurement in the patient. Consequently, the $CTDI_{vol}$ does not account for size differences or other patient-specific factors. The radiation risk more closely correlates to the actual amount of radiation (energy) transferred to the patient. The dose length product (mGy-cm) is the product of the z-axis length and the $CTDI_{vol}$ (integrated radiation dose from acquiring a single scan divided by the total nominal scan width or beam collimation), as displayed in Equation 40.2. Although the DLP correlates to the total radiation dose, this parameter is not a substitute for the effective radiation dose because the DLP does not account for the radiosensitivity of the organs in the irradiated tissues as the effective radiation dose does.

$$\text{Dose length product (DLP)} = CTDI_{vol} \times \text{length of } z\text{-axis } (L) \quad \text{(Equation 40.2)}$$

TABLE 40.7. Estimated median and range of Dose Length Product (DLP) (mGy-cm) for noncardiac CT scans in a study of the medical literature from 1991–2009. (Data from Pantos et al.).[41]

CT Examination	Median DLP (mGy-cm)	Range DLP (mGy-cm)
Head	733	81–2,173
Chest	394	21–2,286
Abdomen	464	58–2,537
Pelvis	434	67–2,000
Abdomen/pelvis	472	430–1,850
Cervical spine	324	56–1,275
Thoracic spine	253	66–515
Lumbar spine	302	49–870

The effective dose can be calculated from the DPL on the CT scanner by using a conversion factor k (mSv/mGy-cm), as displayed in Equation 40.3. This conversion factor varies with several factors including X-ray tube voltage, age/size of the patient, body region, and CTDI phantom (10 cm, 16 cm, 32 cm diameter) used to calculate the DLP displayed on the scanner. Effective doses for different body regions derived from Monte Carlo calculations may differ from the values derived from the dose length product (DLP), depending on the source of the conversion factors:[52]

$$\text{Effective dose } (E) = \text{DLP} \times k \qquad \text{(Equation 40.3)}$$

where

k = conversion factor (mSv/mGy-cm).

In a study of 636 participants in the International Atomic Energy Agency Research Coordination Project, the average dose length product was 544 mGy/cm for head CT scans compared with 348 mGy-cm for chest CT scans and 549 mGy-cm for abdominal CT scans.[49] Table 40.7 lists the estimated median and range of the DLP in a study of values for noncardiac CT scans reported in the medical literature from 1991–2009. The data indicate substantial variation in the DLP between medical institutions.

Children

Pediatric CT scans account for ~10% of the total number of CT examinations. The effective and organ doses depend on the patient's size and organ mass because the smaller size of younger children increases the average organ effective dose in the irradiated region.[53] A neonate may receive a radiation dose for a single CT scan that is over double the amount received by an adult, depending on the scanner settings.[6] The effective dose also varies substantially between different studies and institutions. The calculated effective dose ranged from 0.03–69.2 mSv in a retrospective observational study of 744 pediatric CT scans performed on children <15 years at 7 large US HMO organization from 2001–2011.[54] The effective dose exceeded 20 mSv in 14–25% of abdomen/pelvis CT scans, 6–14% of spine CT scans, and 3–8% of chest CT scans. In a study of infants under 2 years of age, the average effective dose for head CT scans was 7.6 ± 3.1 mSv compared with 1.3 ± 0.1 mSv for adults. The effective doses in body CT scans can be 2-fold greater in children and 4-fold greater for newborns than adults. In a study of patients undergoing abdominal CT scans, the mean effective dose for children (≤10 years) was 6.1 ± 1.4 mSv compared with 4.4 ± 1.0 mSv for young adults (11–18 years) and 3.9 ± 1.1 mSv for adults (>18 years).[55] The median (interquartile range) of effective radiation doses in 3,871 pediatric CT scans during the large University of California study were reported for the following body regions: head, 2 mSv (1–4 mSv); chest, 3 mSv (2–5 mSv); abdomen, 4 mSv (3–7 mSv); chest/abdomen, 9 mSv (5–15 mSv); sinus, 1 mSv (1–2 mSv); and neck, 4 mSv (2–6 mSv).[50] Recently, CT usage decreased in pediatric patients in favor of ultrasound and MRI imaging.

CT scanning accounts for a relatively large portion of the average radiation dose from medical procedures compared with the number of CT examinations. Organs in the direct beam receive the highest dose of radiation.[56] In a UK survey during the early 1990s, an abdominal CT delivered more radiation than a barium enema and ~8 times the effective radiation dose from a conventional abdominal X-ray examination.[57] In this survey, the average delivered dose for head CT was 3–4 mSv (range 1–10 mSv) and 8.8 mSv for abdominal CT. New techniques reduce the effective radiation dose of relatively high-radiation procedures (e.g., multislice cardiac computed tomography angiography). In a collaborative radiation dose-reduction program, the median effective dose for cardiac computed tomography decreased from 21 mSv (IQR, 12–26 mSv) to 10 mSv (IQR, 6–16 mSv).[58] A study of CT scans on 100 consecutive pediatric neurosurgical patients ($\text{Mean}_{\text{age}} = 6.75$ years) during the late 1980s indicated the average ocular lens dose from a CT scan was 42 mGy with a cumulated dose ranging from 0–1.43 Gy ($\text{Mean}_{\text{scans}} = 7.75$, range 0–34).[59]

Conceptus

The dose to the conceptus (i.e., embryo/fetus from time of conception to birth) depends on the particular

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. 	Cerebral blood flow (^{99m}Tc-HMPAO, 740 MBq)	3–6.7
	Lung-ventilation (^{133}Xe, 740 MBq)	0.02–0.3
	Lung-perfusion (^{99m}Tc-MMA, 148 MBq)	0.4–0.7
	Myocardial perfusion (^{99m}Tc-sestamibi, 1,110 MBq)	5–6
	Renal scan (^{99m}Tc-MAG3, 370 MBq)	1.9–6.7
	Bone scan (^{99m}Tc-MDP, 740 MBq)	1.5–4.4
	Positron-emission tomography (PET) scan (^{18}F-FDB, 740 MBq)	13–16
Radiotherapy	Cancer therapy – 5% uptake (^{131}I, 3,700 MBq)	66–1,000
	Benign therapy – 50% uptake (^{131}I, 555 MBq)	40–150

Abbreviations: FDG = fluorodeoxyglucose; HMPAO = hexamethylpropylene amine oxime; MAA = macroaggregated albumin; MAG3 = mercaptoacetyltriglycine; MDP = methylene diphosphonate.

[a] Anatomical coverage is the same as for routine abdominopelvic CT, but the tube current is decreased and the pitch is increased because standard image quality is not necessary for the detection of high-contrast stones.

radiographical examination, technical factors (time, photon energy, intensity), number/type of projections, and maternal anatomy (abdominal thickness, uterine location/size/orientation, urinary bladder volume). Table 40.8 displays typical radiation doses to the conceptus (embryo/fetus) for selected medical procedures; the conceptus dose is typically substantially less than the maternal whole-body dose because the tissues between the maternal skin and the conceptus attenuate the radiation dose. The conceptus dose during fluoroscopy-guided interventional procedures, some CT scans, and radiotherapy frequently is much higher than during conventional radiographical examination; a qualified expert typically should evaluate the conceptus dose during these examinations.

During the first 2 months of pregnancy, the conceptus dose is equivalent to the maternal uterine dose. As the pregnancy advances, the conceptus dose becomes less uniform, requiring correction factors to convert the maternal uterine dose to the conceptus dose.[61] The *potential* effects of ionizing radiation exposure on the embryo or fetus involve deterministic and stochastic effects including growth retardation, congenital malformations, miscarriage, and cancer (primarily leukemia). The risk of these adverse effects is related to the *in utero* dose and the developmental period during the time of radiation; a threshold may exist for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the deterministic effects. Case reports involving older therapeutic procedures suggest that large doses of fetal radiation (e.g., 888 rads during the sixth month of gestation) during the less radiosensitive second and third trimesters do not always produce fetal abnormalities.[62] The maternal tissue attenuates the energy of X-ray photons; subsequently, the fetus receives ~20% of the radiation dose absorbed by the skin on the maternal abdomen.[63] The risk of developing fetal abnormalities following *in utero* radiation doses after single diagnostic procedures (<50–100 mGy) is small compared with the other risks during pregnancy.[64] Fluoroscopic procedures deliver much higher radiation doses (i.e., 50 mGy/minute to the maternal abdomen equates to ~10 mGy/minute to the fetus) than conventional X-rays; consequently, the potential risk to the developing fetus is greater during fluoroscopy than conventional X-ray examinations. The dose absorbed by the fetus depends on the direction of the X-ray beam. The contribution of conventional X-rays (e.g., skull, neck, chest, and extremities) directed more than 10 cm from the fetal area is minimal.[65] Most diagnostic radiation procedures deliver a fetal absorbed dose of <1 mGy for imaging beyond the abdomen/pelvis and <10 mGy for direct scans or nuclear medicine imaging.[66] CT scans deliver higher fetal doses. Directing the X-ray beam directly on the embryo during abdominal CT scanning of pregnant patients results in radiation doses in the embryo of 10–35 mGy.[67]

The use of fluoroscopically or CT-guided interventional procedures in the pelvis potentially increases the risk of teratogenesis because the delivered dose may exceed the teratogenic threshold of >100 mGy, depending on the procedure.[68] All such procedures should be optimized to limit the radiation dose to the minimum amount necessary to achieve the clinical purpose of the procedure given the available technology and resources. Guidelines are available from American and European interventional radiology associations to control the radiation dose to the mother and conceptus.[68] Interventional procedures in anatomical regions remote from the conceptus (e.g., skull, chest, extremities) are typically performed safely at any time during pregnancy with proper collimation.[67] Table 40.9 lists typical and reported ranges for the conceptus radiation doses from common interventional procedures.

The most common indications for CT imaging during pregnancy are maternal trauma resulting in

TABLE 40.9. Typical and reported ranges of conceptus radiation doses from common fluoroscopic and angiographic procedures. (Adapted from Dauer et al.).[68]

Examination	Typical Estimate (mGy)	Reported Range (mGy)

a positive Focused Assessment with Sonography in Trauma (FAST) examination and suspected pulmonary embolism.[69,70] In general, fetal radiation from maternal CT of the head, neck, and extremities excluding the hips is minimal, whereas the fetal radiation dose becomes more concerning when the fetus is in the field of view.[71]

CLINICAL RESPONSE

Postcontrast Acute Kidney Injury

Postcontrast acute kidney injury (contrast-associated or contrast-induced nephropathy) is a reduction of renal function usually occurring within 48–72 hours after the administration of iodinated contrast medium during medical imaging procedures. Typically, an increase in serum creatinine of 0.3–0.5 mg/dL or 25% of baseline serum creatinine values within 2–5 days following contrast-enhanced computed tomography, coronary angiography, or percutaneous coronary procedures defines this complication. The decline in kidney function is typically reversible. The incidence ranges from ~1–20% depending on the population studied, the outcome measure of postcontrast acute kidney injury, and the type of contrast administered with the incidence in the lower range using current precautions.[72] Suggested risk factors for postcontrast acute kidney injury include diabetes, heart failure, hepatic failure, preexisting renal disease, advanced age, and multiple myeloma (hypercalcemia); however, the issue of whether contrast-associated acute kidney injury is a cause or a biomarker of adverse renal outcomes remains unclear.[73] The risk of acute renal injury in patients without these potential risk factors is not well defined; recent studies suggest these risks may have been overestimated.[74] Residual confounding and indication bias complicate the interpretation of epidemiology studies on postcontrast acute kidney injury with recent studies suggesting little evidence of reduced kidney function after intravenous contrast for CT pulmonary angiograms in emergency settings. Potential pathological mechanisms involve direct cytotoxicity to tubular epithelial cells, renal vasoconstriction/tissue hypoxia secondary to vasomotor changes, increased oxidative stress, and blood hyperviscosity.

Potential risk factors for postcontrast acute kidney injury include severe chronic kidney disease, high-osmolality contrast, repeated contrast administration within 3 days, and ST-segment elevated myocardial infarction. A meta-analysis of 28 observational, primarily retrospective studies did not detect a statistically significant difference between noncontrast and contrast-enhanced CT for the development of acute kidney injury (OR = 0.94, 95% CI: 0.83–1.07) or the necessity for postcontrast renal replacement therapy.[75] Only 1 of the 28 studies involved the use of high-osmolar contrast agents. A retrospective, propensity-matched, case-control study did not detect a statistically significant difference in the incidence of subsequent acute kidney injury between 7,201 patients undergoing contrast-enhanced CT and controls (5,499 patients undergoing unenhanced CT; 5,234 ED patients without imaging) after adjustment for patient demographics and risk factors.[76] The rate of later acute renal injury in these three groups ranged from 10.2–10.9%. The development of postcontrast acute kidney injury after contrast-enhanced radiographic studies correlates to the administration of large volumes of high osmolality contrast medium to patients with significant preexisting kidney disease. The most important mitigating factor is IV hydration (1–1.5 mL isotonic saline/kg/hour) up to 6–12 hours before and 4–12 hours up to 24 hours after the procedure. A shorter protocol (1–3 hours before and 6 hours after the procedure) may be more practical for urgent situations.[77] The volume of intravenous fluid required to prevent acute kidney injury in patients undergoing contrast-enhanced imaging is not well defined. The withdrawal of medications that reduce renal function (e.g., angiotensin II receptor blockers, angiotensin-converting enzyme inhibitors, diuretics, nonsteroidal anti-inflammatory drugs) was recommended. Evidence for the efficacy of other methods to reduce postcontrast acute kidney injury is insufficient. Isotonic sodium bicarbonate probably provides little benefit compared with isotonic saline, whereas acetylcysteine and statins are not routinely recommended for the prevention of postcontrast kidney injury.[74]

Deterministic Effects (Tissue Reactions)

Deterministic effects (near term, tissue reactions) involve the consequences of radiation-induced cell death (e.g., skin erythema/ulceration, acute radiation sickness), whereas stochastic effects involve cell damage (e.g., cancer, heritable effects). Potential deterministic effects (tissue reactions) for the developing embryo/fetus include miscarriage, stillbirth, growth retardation, microcephaly, mental retardation, neurobehavioral abnormalities, reduced intelligence (IQ), seizure disorders, and congenital malformations. For deterministic effects, the severity and incidence of the effects increase with dose, whereas the incidence of stochastic effects also increases with dose, but the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

radiation dose does not correlate to the severity or magnitude of the effect. The radiation dose from diagnostic X-ray procedures is small compared with radiation doses necessary to produce acute radiation effects; the whole-body radiation dose (i.e., 1–2 Gy) associated with the development of mild-moderate acute radiation sickness including nausea and vomiting is ~50,000–100,000 higher than a single PA chest X-ray (0.02 mSv). The main concern regarding deterministic effects from medical imaging involves skin damage from interventional procedures, particularly complex fluoroscopy-guided interventional procedures requiring long fluoroscopy times to acquire numerous images. Some studies suggest that exposure to thyroid radiation doses of 400–800 mGy during the first trimester may cause a slight reduction in birth weight.[78] Prolonged fluoroscopic imaging during procedures may cause radiation-induced skin injuries in the patient. Threshold doses for the development of skin injuries depend on several factors (i.e., age, fractionation of dose, area of skin); typical threshold entrance radiation doses include ~3 Gy for temporary epilation, ~6 Gy for erythema, and ~15–20 Gy for moist desquamation, ulceration, and dermal necrosis.[79]

Carcinogenesis

Childhood cancers represent <1% of total cancer occurrence with leukemias, brain tumors, and lymphomas representing ~70% of pediatric cancers.[80] Most epidemiology studies on *in utero*/early childhood cancer risks are case-control designed; statistical limitations of these epidemiology studies (rare diseases/low power, recall/reporting bias from questionnaire/interview data) create uncertainty over small changes in leukemia incidence following low-dose ionizing radiation exposure.[81] The detection of the leukemogenic effects following exposure to 100 mGy based on BEIR III data requires a control and an irradiated population size of 160,000.[82] The cohort size increases to 8 million following exposure to 10 mGy. Selection bias, racial differences in health experience, limited animal evidence of low-dose carcinogenic effects, and the limited low-dose data from Hiroshima and Nagasaki complicate the interpretation of data regarding the association between threshold radiation doses from diagnostic X-rays and leukemia risk.[83,84,85] Analysis of Japanese atomic bomb data indicates the lifetime risk of cancer may be considerably lower following *in utero* radiation exposure than in early childhood.[86]

Leukemia

In Utero Exposure

The association between diagnostic X-rays and childhood leukemia following *in utero* exposure is strongest for studies from the 1970s and 1980s, whereas the inclusion of later studies (i.e., with smaller radiation doses <100 mSv) reduces the risks to borderline or not statistically significant.[87,88,89] The current evidence for an association between maternal diagnostic X-rays prior to conception and a subsequent increase in the incidence of leukemia is minimal, whereas studies of *in utero* diagnostic X-ray exposure before the 1970s suggest a small increase in the leukemia incidence in these children. Case-control studies of 8,513 offspring of pregnant women receiving estimated antenatal radiation doses of 10–100 mGy during pelvimetry in the 1950s and 1960s (Oxford Survey of Childhood Cancers) indicated the relative risk of death from leukemia in these children increased by a factor up to 1.5–2.0, especially following self-reported *in utero* irradiation during the first trimester.[90,91] The risk of cancer decreased later in the study as the fetal dose from pelvic X-rays decreased; however, the risks of leukemia-related mortality in these children were relatively uniform across all tumors including both radiosensitive and radioresistant tumors. Cases were based on the recall of abdominal radiographs by the mothers during pregnancy; the actual effective radiation doses were not quantitated.[92] In a review of medical records of >32,000 twins born between 1930–1969, 31 cases of cancer including leukemia were matched with 4 twin controls based on sex, year of birth, and race. Only low birth weight was associated with an increased incidence of cancer.[93] After adjusting for low birth weight, the relative risk of cancer in the twins was marginally increased (RR = 2.4; 95% CI: 1.0–5.9). The increased leukemia incidence following *in utero* radiation occurred almost exclusively in children born to mothers with previous abortions. Other case-control studies[94] and negative studies with limited statistical power[95] suggest the actual increased childhood leukemia risk is near 1.4.[96]

The current effective radiation doses delivered by obstetric X-rays have decreased significantly compared with X-ray examinations before 1995. Acute lymphoblastic leukemia (ALL) is the most common childhood cancer in developed countries, with most cases diagnosed prior to 5 years of age. A case-control study of 389 cases of ALL and 876 frequency-matched controls conducted from 2003–2006 did not detect evidence of an increased ALL risk in fetuses receiving *in utero* radiation exposure from maternal abdominal or pelvic X-rays after adjustment for study matching

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

factors and potential confounders using unconditional logistic regression.[97] The odds ratio for ALL following any diagnostic X-rays (i.e., plain X-ray, CT scan, intravenous pyelogram, barium study) during pregnancy was 0.46 (95% CI: 0.15–1.40).

Paternal Exposure

Evidence on leukemia risks of paternal diagnostic X-rays prior to conception is equivocal. A preliminary review of the Oxford Study data on childhood cancer and paternal exposure does not demonstrate *paternal* radiation exposure was a significant factor in the development of childhood cancer; the association between postnatal exposure to medical diagnostic radiation and childhood leukemia remains inconsistent.[87,98] The Children's Cancer Group study did not detect elevated risks of childhood ALL following maternal (OR = 0.9, 95% CI: 0.8–1.2) or paternal (OR = 1.1, 95% CI: 0.8–1.4) self-reported radiation exposure from lower abdominal preconception diagnostic X-rays.[10] A meta-analysis of paternal radiation exposure from abdominal X-rays prior to conception did not detect a statistically significant elevated risk of leukemia in offspring with a pooled OR of 1.17 (95% CI: 0.92–1.48).[97] The study suggested >1 paternal abdominal X-ray (OR = 1.47, 95% CI: 0.98–2.21; $n = 46$) or paternal intravenous pyelogram may increase ALL risk (OR = 3.56, 95% CI: 1.59–7.98; $n = 16$).

Postnatal Exposure

The Japanese atomic bomb survivor data indicate that young children are more sensitive to the development of radiation-induced leukemia than adults, with the risk increasing within a few years after exposure. Acute lymphoblastic leukemia is the most common type of childhood cancer in developed countries; the evidence from case-control studies for an association between childhood leukemia and postnatal exposure to medical diagnostic irradiation is equivocal and conflicting. Epidemiology studies of healthy infants receiving radiation for enlargement of the thymus and scalp radiation for *Tinea capitis* suggest an increased incidence of leukemia, whereas studies of infants irradiated for skin hemangiomas did not clearly detect a raised childhood leukemia risk, despite radiation doses near the level producing childhood leukemia in the LSS study of Japanese survivors.[99] In a case-control study (The Children's Cancer Group) of 1,842 ALL cases diagnosed under the age of 15 years, the risk of pediatric ALL was not elevated (OR = 1.2, 95% CI: 0.8–1.7) based on self-reported parental preconception, *in utero*, and postnatal X-ray exposure.[10] A cohort study of 92,957 children receiving diagnostic X-rays in a large German hospital 1976–2003 did not detect an elevated cancer risk from this radiation exposure.[100] The standardized incidence ratio (SIR) for all cancers was 0.99 (95% CI: 0.79–1.22) with multivariate Poisson regression detecting no trend in the incidence of total cancer, leukemia, or solid tumors with increasing radiation dose. The median radiation dose was relatively low (i.e., 7 μSv).

Other studies suggest a small increased risk of leukemia in children irradiated during childhood. A California case-control study of 711 cases of ALL and 116 cases of acute myeloid leukemia (AML) in children up to 18 years demonstrated an elevated risk of B cell ALL (OR = 1.40, 95% CI: 1.06–1.86) in children with reported postnatal X-rays; the risk was independent of the region of the body radiated.[87] However, the risk increased with the number of reported X-rays. The study did not detect an increased risk of T cell ALL (OR = 0.84, 95% CI: 0.59–1.19) or AML (OR = 1.05, 95% CI: 0.90–1.22) in irradiated children. Similarly, a retrospective case-control study of 412 Southern Californian children with AML did not demonstrate an association between AML risk and high-dose (≥1 mSv), low-dose (<1 mSv), or the number of postnatal diagnostic X-rays.[101]

In a population-based, cohort study of 680,000 Australian children and adolescents up to 19 years of age undergoing CT scans from 1985–2005, the incidence rate ratio (IRR) for all leukemias was 1.19 (95% CI: 1.03–1.37, $P < 0.001$) compared with unexposed children.[102] The exposed group had at least one CT scan (mean average effective radiation dose/scan = 4.5 mSv) >1 year prior to their cancer diagnosis; the mean duration of follow-up was 9.5 years. The excess rate ratio/mGy for leukemia and myelodysplasias based on a 1-year lag was 0.039 (95% CI: 0.014–0.070). The IRR for all cancers was 1.24 (95% CI: 1.20–1.29, $P < 0.001$). The relatively short follow-up for solid tumors suggests the risk may be greater for this group. Limitations of the study include the lack of clinical indications for testing and the possibility of concurrent cancer, short latency periods, uncertain dose calculations in the early part of the study, and the lack of positive results in radiosensitive tissues (e.g., breast).

The ERR values from the Australian study and the UK retrospective, record-based cohort study of 178,604 subjects under the age of 22 years were similar; the excess relative risk/mGy of leukemia with follow-up beginning at 2 years and lasting for an average of 7.3 years was 0.036/mGy (95% CI: 0.005–0.120; $P = 0.0097$).[103] The relative leukemia risk increased for patients receiving cumulative radiation doses of >30 mGy. For these patients (mean = 51.13 mGy), the relative risk of leukemia was 3.18 (95% CI: 1.46–6.94)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

compared with patients receiving <5 mGy. The data were consistent with a linear model rather than linear-quadratic or linear-exponential models for leukemia. The cumulative absolute risks are small because of the rarity of these cancers. The average follow-up was ~10 years, which is a sufficient lag time for leukemia (but not for solid tumors like the brain). The studies did not include medical conditions of the participants, raising questions about reverse causation; substantial uncertainty exists concerning the assigned radiation doses because of the lack of individual dosimetry. In a case-control study of 2,960 children with cancer and 4,858 age, sex, and region-matched controls from the United Kingdom, the odds ratio for all leukemias was marginally elevated but statistically nonsignificant (OR = 1.20, 95% CI: 0.91–2.02). The odds ratio for leukemia in cases and controls was not statistically different.[104] Most of these children received radiation doses of <1 mSv.

There are fewer epidemiological data on the radiation risk from CT scans in adults. A well-designed case-control study of adult patients with leukemia, lymphoma, and multiple myeloma in two prepaid health plans did not demonstrate a statistically significant increase in these tumors after follow-up of 15 years for 1/3 of the patients who remained in the cohort.[105] Based on data from Hiroshima and Nagasaki, excess leukemia cases following irradiation begin 2–4 years after exposure, peak at ~6–8 years, and decrease to baseline rates at 25 years.[106] Consequently, the patients were not followed for the whole latency period of these tumors; no power calculations were done to determine how much of the leukemia risk could be excluded. There was no dose-related increase in the incidence of leukemia or lymphoma, but the risk of multiple myeloma did increase among patients with frequent X-ray exposure.

Breast

Following exposure of women to radiation doses exceeding current standards, an elevated risk of breast cancer occurred in atomic bomb survivors,[107] X-ray fluoroscopy of the lung for the treatment of tuberculosis,[108] radiation treatment of malignant and benign breast disease,[109] and radiotherapy for Hodgkin's disease.[110] In a health survey of 105,385 female radiology technologists, >50% of the reported breast cancers were attributed to recognized risk factors (early age at menarche, first-degree relative with history of breast cancer, >14 alcoholic drinks/week, hyperthyroidism, and estrogens).[111] This study did not detect an elevated risk of breast cancer in technologists receiving long-term exposure to low levels of ionizing radiation including employment involving radiotherapy, radioisotopes, and fluoroscopic equipment. In a US prospective cohort of 90,957 radiology technologists responding to a 1994–1998 survey on fluoroscopically guided interventional procedures and followed to 2003–2005 for cancer incidence and 2008 for cancer mortality, breast cancer incidence was slightly increased (Hazzard Ratio = 1.16; 95% CI: 1.02–1.32) when compared with radiology technologists never using fluoroscopes.[112] Breast cancer mortality was not increased (HR = 1.07; 95% CI: 0.69–1.66) among technologists performing fluoroscopically guided interventional procedures. The Australian cohort study of patients under 19 years of age did not detect an excess risk of breast cancer in children undergoing CT scanning during their childhood (IRR = 0.99; 95% CI: 0.83–1.17).[102]

Brain

The results from case-control studies on meningioma risks and exposure to dental X-rays are conflicting, with more recent studies failing to confirm prior positive studies. In a retrospective case-control study of 200 histologically confirmed meningiomas and 400 age- and sex-matched population controls, in-person interviews determined dental X-ray history for classifying exposure into dental X-ray categories (full-mouth series, posterior bitewings, panoramic views, lateral cephalometric views) and number of examinations.[113] The odds ratio was statistically significant only for ≥6 full-mouth series (OR = 2.06, 95% CI: 1.03–4.17); however, the trend for increasing examinations did not demonstrate a dose-response relationship ($P_{\text{trend}} = 0.33$). Studies published in the 1950s estimated the radiation dose during full-mouth radiographical examination were ~1.15–2.8 Gy.[114]

Several large observational studies of children receiving CT scans report that high brain radiation doses from head CT scans (20–50 mGy) may cause a small, statistically significant excess absolute risk of brain tumors but not leukemia. The Australian cohort of patients under 19 years of age reported an excess risk of brain cancer following CT scans involving the brain and other organs.[102] The IRR for brain cancer was 2.31 (95% CI: 1.88–2.41); the excess rate ratio (ERR)/mGy was 0.021 (95% CI: 0.014–0.029). The Dutch Pediatric CT Study included 106,530 children in the solid tumor analyses and 140,612 children in the leukemia analyses.[115] The standardized cancer incidence was elevated for all sites (SIR = 1.47, 95% CI: 1.34–1.61, $n = 454$ cases), all CNS tumors (SIR = 2.05, 95% CI: 1.48–2.83, $n = 37$ cases), and hematolymphoproliferative cancers (SIR = 1.39, 95% CI: 1.13–1.70, $n = 93$ cases). The relative risk in the highest radiation exposure category

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(>120 mGy) for malignant brain tumors with a 5-year lag (RR = 1.02, 95% CI: 0.01–4.30, $n = 8$ cases, $P = 0.047$) was statistically significant. The mean follow-up period was ~8 years. These results represented 1 excess brain tumor (malignant and nonmalignant) per 10,000 pediatric CT scans projected to cause 1 of the 120 brain tumors occurring in the Dutch pediatric population annually. The authors opined that the results should be interpreted cautiously because of the small number of cases and shorter latency period for a solid tumor than current evidence suggests. The study did not detect excess leukemia risks in children receiving CT scans with a mean cumulative radiation dose of 9.5 mGy. The UK retrospective cohort study described above also demonstrated an elevated brain cancer risk following CT scans with a 5-year lag time and mean follow-up of 7.3 years.[103] The excess relative risk/mGy was 0.023 (95% CI: 0.010–0.049). The relative risk of brain cancer for patients receiving a cumulative dose of 50–74 mGy (mean = 60.42 mGy) was 2.82 (95% CI: 1.33–6.03) compared with patients receiving <5 mGy. The US prospective cohort of 90,957 radiology technologists demonstrated a ~2-fold increased risk of brain cancer mortality in technologists using fluoroscopy (HR, 2.55; 95% CI: 1.48–4.40).[112] Leukemia incidence and mortality were not increased in the radiology technologists using fluoroscopy.

Reproductive Abnormalities

Birth defects, mental retardation and other neurobehavioral effects, growth retardation, and embryonic demise are deterministic effects with thresholds and no adverse effect levels (NOAEL). These adverse effects occur spontaneously in the general population without radiation exposure above natural background; Table 40.10 demonstrates the approximate spontaneous risk of common reproductive abnormalities to the embryo at conception.

Growth retardation, gross congenital malformations, and embryo demise are classic effects of large radiation doses in mammals. Animal studies indicate estimated embryonic radiation doses in the range of 150–200 mGy during the preimplantation and presomite stages may increase the risk of embryonic loss; however, the surviving embryos do not demonstrate an increased risk of congenital malformations or growth retardation.[116] Embryonic and fetal radiation doses of <100 mSv are not clearly associated with an increased risk of deterministic effects (tissue reactions) in humans including the risk of severe mental retardation at any stage of pregnancy. Microcephaly was the most common malformation

TABLE 40.10. Spontaneous risk of adverse effects on the embryo at conception with no radiation above natural background. (Adapted from Dauer et al.).[68]

Adverse Reproductive Effect	Approximate Spontaneous Risk
Pregnancy loss before first missed menstrual period	1/3
Spontaneous abortion during known pregnancy	1/7
Genetic disease	1/10
Prematurity	1/25
Growth retardation	1/33
Major congenital malformation	1/33
Stillborn birth	1/50–1/250
Severe mental disability	1/200
Childhood leukemia risk per year	1/25,000
Infertility	1/15 couples

developing after the exposure of pregnant women at Hiroshima and Nagasaki to fetal doses of radiation of >1 Gy during the most radiosensitive period (8th–15th week postconception).[117] No radiation-induced malformation developed without the presence of growth retardation or a central nervous system abnormality. Almost all diagnostic radiological procedures of the head, neck, chest, or extremities deliver radiation doses below the NOAEL for these developmental effects.[118] Table 40.11 lists the effects of radiation during various gestational times with estimated thresholds for deterministic effects.

Small case-control studies of women exposed to diagnostic X-rays during pregnancy have not demonstrated statistically significant elevations in the risk of congenital malformation in the offspring, the risk of spontaneous abortion, or reduced fertility in the mother.[119,120] A case-control study of female veterinarians did not demonstrate an increased incidence of self-reported spontaneous abortions or low birth weight infants compared with a control group of female lawyers; however, a weak positive association occurred between the greater use of X-rays and the number of spontaneous abortions in the female veterinarians.[121] Reported birth defects were higher among the veterinarians than the lawyers (RR = 4.2, 95% CI: 1.2–15.1) after controlling for confounders. The findings were unexpected and considered hypothesis-generating by the authors, reflecting the wide confidence interval.

The determination of the risk of developing these abnormalities depends on the extrapolation with mathematical models of high-dose data from Hiroshima and Nagasaki to the radiation dose produced by diagnostic X-rays. The development of severe mental retardation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 40.11. Radiation effects associated with various stages of gestation. (Based on Brent).[118]

Stage[a]	Effect
3rd–4th (first 2 weeks postconception)	Most sensitive time for embryonic demise. Animal studies suggest threshold of 100–200 mGy.
4th–8th (2–6 weeks postconception)	Embryo is susceptible to major malformations and growth retardation with minimal threshold for growth retardation near 200–500 mGy.
8th–15th	Most sensitive time for irreversible whole-body growth retardation, severe mental retardation, and microcephaly. The threshold for severe mental retardation is ~350–500 mGy with a potential for decreased IQ at lower radiation exposures (100–350 mGy).
16th–term	High radiation exposure can produce growth retardation and reduced brain size/intellect; however, the effects are less severe than during midgestation. The risk of major anatomical malformation is minimal. Threshold for severe mental retardation of >1,500 mGy with ↓ IQ potentially occurring at lower radiation doses. After the 25th week, the central nervous system is relatively radioresistant; major fetal malformations and functional anomalies are unlikely.

[a] Weeks after first missed menstrual period.

following the doses of radiation produced by diagnostic X-rays is unlikely, in part, because a threshold for the development of this abnormality probably exists far above standard levels of medical radiation.[71,122]

DOSIMETRY

Analytical Methods

Determination of the radiation dose delivered by CT is a complex process involving the quantification of the nonhomogeneous distribution of radiation inside the patient that results from each slice of tissue receiving radiation during direct scanning *and* indirectly from the scanning of adjacent tissue. The best measure for risk estimation is the organ dose; however, the mean absorbed radiation dose in organs or tissues of patients undergoing medical imaging cannot usually be measured directly.[8] Consequently, quantification usually requires measurements in cylindrical phantoms containing dosimeters (e.g., pencil ionization chambers with an active length of 100 mm) rather than direct measurements in the patient. The radiation dose from a CT examination depends on a variety of technical factors involving scanner design and clinical protocols including single-scan image quality, the number of scans per examination, slice scan time, scan pitch (i.e., degree of overlap between adjacent CT slices) and motion, multiple-scan geometric efficiency, axial scan range, tube voltage (kVp), X-ray beam filtration and collimation, and efficiency of the detector. [123,124] Consequently, the CT radiation dose differs between commercial CT scanners depending on the design of basic imaging parameters (i.e., scan noise, slice thickness/spacing, transverse spatial resolution as measured by pixel width).[124] The accidental loss of the aluminum filter increased the surface (entrance) dose by 24% and the center dose by 18% for head CT; the loss of the filter also enlarged the surface dose by 25% and the center dose by 16% for CT of the body.[125] The operator can adjust the radiation dose by controlling X-ray tube voltage (kVp), tube current and scan time (mAs), table pitch (table speed in longitudinal *z*-axis), detector configuration, and gantry rotation time.[126] Increasing the table pitch or gantry rotation and reducing the tube voltage decreases the radiation dose.

Hospital medical physicists and health physicists are resources for radiation dose estimation including delivered fetal and adult radiation doses. Other US resources include contacts for state radiation/control radiation experts (Conference of Radiation Control Program Directors, http://www.crcpd.org), active certified health physicists (American Board of Health Physics, https://www.aahp-abhp.org), and diplomats in medical physics specialties (American Board of Medical Physicists, http://www.abmpexam.com).

Diagnostic Reference Levels

Diagnostic reference levels for radiographs (DRLs for interventional procedures) were introduced as an advisory value to assist in the optimization of medical imaging and the radiation dose to the patient by identifying radiological practices that regularly exceed most other similar practices.[127] The UK National Patient Dose Database has collected data on radiation dose from common radiographical and fluoroscopic X-ray examinations since the mid-1980s; these data indicate a progressive decline in the entrance surface dose (ESD) to less than half the original levels.[13,128] The ESD (third quartile value) for AP lumbar spine declined from 10 mGy in the mid-1980s to 6 mGy in 2000. The current diagnostic reference level (75% upper

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

limit) for this examination is 4.2 mGy. Low-radiation dose images may also be detrimental to patient care when inadequate image quality (e.g., excessive noise levels) reduces the clinical effectiveness of the imaging. Diagnostic reference levels and achievable doses are dynamic values that change with time and technological innovations. The US National Council for Radiological Protection and Measurements (NCRP) establishes DRLs using data for ionizing radiation doses provided by the Nationwide Evaluation of X-Ray Trends (NEXT) Program. The NEXT Program is a cooperative effort between the US Food and Drug Administration (FDA), state radiation control offices through the Conference of Radiation Control Program Directors, Inc., and the American College of Radiology. Table 40.12 lists the diagnostic reference levels and achievable doses recommended by the NCRP. Public Health England provides a list of recommended national diagnostic reference levels (NDRLs) for pediatric and adult diagnostic radiological examinations, CT scans, fluoroscopy, and interventional procedures.[129]

These values are established to indicate the need to review radiological practices; exceeding the DRL does necessarily imply an unacceptable practice or the need to change the practice.[8] Typically, the DRL uses quantities that are easy to measure (e.g., entrance surface dose, entrance surface air kerma, dose-area product) with the value set at the upper 75%. Achievable doses are usually set at 50%. For conventional radiography, surveyed radiographs include various projections of skull, chest, abdomen, spine, and pelvis. The pediatric DRL varies with age.

For comparison with US values, Table 40.13 lists diagnostic reference levels, tube potentials, and backscatter data from the UK Health Protection Agency for selected radiographical examinations. The absolute magnitude of DRLs in Europe varies from country to country because the values are based on local surveys of patient doses; therefore, the DRLs are not directly comparable to NCRP values based on a more uniform phantom-based approach.

Biomarkers

Determination of the incidence of chromosomal abnormalities is usually done by cytogenetic metaphase analysis of chromosomes from circulating lymphocytes. Chromosomal abnormalities do not usually occur above the normal rate of ~1% until the whole-body radiation dose exceeds 100–300 mSv; consequently, typical radiation doses from medical imaging are not associated with chromosomal abnormalities.[131] Cytogenetic analysis may be useful as a negative indicator to demonstrate the whole-body dose did not exceed a specific level or the observed adverse effects do not correlate to

TABLE 40.12. US National Council for Radiological Protection and Measurements diagnostic reference levels and achievable doses. (National Council on Radiation Protection and Measurements).[127]

Examination	Units	Diagnostic Reference Level	Achievable Dose
Adult PA chest (with grid)	mGy	0.15	0.11
Pediatric chest			
Without grid	mGy	0.06	0.04

the estimated dose based on the number of chromosomal abnormalities adjusted for patient-specific risk factors.

HEALTH SURVEILLANCE

Risk Assessment

Fetal Development

Although many studies examine the effect of radiation from medical imaging procedures, several factors limit the ability of these studies to quantify risk assessment including small sample size, poor dosimetry, and the difficulty of extrapolating results to a dissimilar population with different baseline cancer rates. Typical fetal doses from diagnostic radiographical procedures are ≪25 mGy. Diagnostic radiological and nuclear medicine procedures do not usually cause significantly increased fetal risks; however, therapeutic procedures and radiotherapy may deliver radiation doses associated with some risk.[132] The greatest risks occur during organogenesis (2nd–8th week postconception) and the rest of the first trimester. The tissue reactions of ionizing radiation (i.e., deterministic effects) include mental retardation, decreased IQ, microcephaly, neurobehavioral effects, convulsive disorders, growth retardation, congenital malformations, and embryonic and fetal death (miscarriage, stillbirth). Animal studies indicate these effects require threshold levels to develop.[60] These studies demonstrate that embryonic doses of 150–200 mGy may increase the risk of embryonic loss during preimplantation or presomite stages (i.e., up to 21 days after fertilization). Surviving embryos receiving these radiation doses have not developed growth retardation or congenital malformations.

Although infants may survive fetal radiation doses of ≥500 mGy without obvious adverse effects,[117] the probability of central nervous system damage and mental retardation becomes substantial at fetal levels over 500 mGy. Except for a Russian study, abnormal pregnancy outcomes in animals and human studies involving fetal radiation doses of <250 mGy are not well documented.[133] During blastogenesis (up to 2 weeks postconception), failure to implant occurs at radiation doses of >500 mGy; embryos that survive radiation exposure during blastogenesis have a low risk of congenital abnormalities because of the pluripotency of the stem cells. Exposure of the embryo to several thousand mGy during early organogenesis causes a significant risk of spontaneous abortion.[113] The risk of severe mental retardation following effective radiation doses of >1,000 mGy is substantial in the $8–15^{th}$ week of gestation as a result of neuronal loss during neuronal migration; however, the risk decreases ~5-fold during the $16–25^{th}$ week of gestation. The development of the central nervous system is much less sensitive to radiation effects during other parts of gestation.[134]

Delivered maternal doses may cause adverse fetal effects following radiation doses insufficient to produce acute maternal effects; a fetal dose of >100 mGy probably causes a some increase in the incidence of deterministic effects (e.g., congenital malformations, growth retardation, fetal demise) depending on the dose. There are no well-documented, radiation-induced, noncancer health effects of <50 mGy.[71,135] Growth retardation occurs at radiation doses of >1,000 mGy with a 3–4% reduction in height by age 17 years.[136] Studies of pregnant mothers irradiated during the bombing at Hiroshima indicate severe mental retardation also may occur *in utero* following radiation doses of >500 mGy during 16–25 weeks postconception.[137] The fetus is particularly sensitive during 8–15 weeks postconception with some IQ reduction above 100 mGy and severe mental retardation and microcephaly above 1,000 mGy during this gestational period.[136] Radiated infants exposed to fractionated *in utero* doses averaging 2,500 mGy developed microcephaly and mental retardation.[138] The sensitivity of the fetus to deterministic radiation effects is lower during the third trimester (>26 weeks postconception) than earlier in the pregnancy, although miscarriage and neonatal death still increase significantly at fetal doses of >1,000 mGy.

Decisions regarding the consequences of diagnostic radiation during pregnancy involve the evaluation of multiple factors listed in Table 40.14.

TABLE 40.14. Factors in the evaluation of radiation exposure during early pregnancy. Any final decision may involve ethical considerations and input from multiple medical specialties.

Factor	Details
Gestational time	Timing of radiation exposure in relation to gestational age and development
Exposure parameters	Projections, number of views, beam quality, kVp, exposure duration, film size, distance of conceptus from beam
Radiopharmaceuticals	Activity, effective half-life, target organs, kinetics, solubility
Dose and risk	Calculation of dose and subsequent risk with input from health physicist as needed
Clinical relevance of examination	Purpose, importance of diagnostic data to outcome, optional imaging, necessity of examination during pregnancy
Fetal/maternal risk factors	Maternal age, genetic factors, maternal disease, social history, past pregnancy complications
Personal factors	Religious beliefs, maternal feelings

Teratogenesis

The most sensitive period for congenital malformation is 22 days postconception with a threshold of 200 mGy.[118] Above this value, the risk of congenital malformation increases; however, the severity remains the same (i.e., an all-or-none phenomenon). The International Commission on Radiological Protection (ICRP) considers radiation doses of >100 mSv as potentially teratogenic with a risk of central nervous system damage, cognitive impairment, and growth retardation.[136] Although conventional X-ray, ventilation-perfusion scanning, and CT pulmonary angiography in a pregnant patient expose the fetus to a relatively small amount of radiation (~4 mSv), the unshielded pregnant woman receives a substantial dose to her breasts. Models predict transgenerational effects from radiation exposure; however, no clear epidemiological evidence associates hereditary effects with radiation exposure. Analysis of data from Japanese atomic bomb survivors did not detect deleterious health effects in 75,327 singleton children born to survivors.[139] The mean gonadal radiation dose was 264 ± 463 mGy; the median follow-up period was 54.3 years (IQR: 45.4–59.3 years). Consequently, the generic risks from low-dose radiation-associated imaging procedures are very small compared with the baseline risks in the population.

Carcinogenesis

Ionizing radiation produces cancer with the risk dependent on the organ-specific dose, age during exposure, and tissue sensitivity (e.g., breast, thyroid, red bone marrow). Radiation-induced cancer does not differ pathologically from other cancer etiologies; therefore, detection of radiation-induced cancer requires epidemiological studies demonstrating increased frequency of cancer incidence and/or mortality in the exposed population. Cancer risks associated with low radiation doses occurring during medical imaging are primarily theoretical with limited epidemiological evidence cancer risks at the low radiation doses (i.e., <100 mGy) produced by radiographical examinations; these risks are usually determined by linear no-threshold models using data extrapolated from the increased cancer incidence and mortality associated with the single, high-dose radiation exposure sustained by Japanese survivors of the atomic bombs dropped in Nagasaki and Hiroshima. The Biological Effects of Ionizing Radiation (BEIR VII) Report predicts a lifetime attributable risk from a 10 mSv effective dose of 1 cancer (solid cancer, leukemia)/1,000 patients based primarily on the linear no-threshold model and Japanese atomic bomb data.[140] However, current epidemiological studies contain large statistical uncertainties that do not provide consistent estimates of radiation risk for whole-body effective doses of <100 mSv, particularly for radiation doses below 10 mSv.[141] Although radiation-induced cancer risks clearly demonstrate a dose-response relationship above 100 mSv, uncertainties substantially increase the range of risks associated with stochastic effects in the range of 100–1,000 mSv with variables including exposure rate, characteristics of the population exposed, and organs/tissues involved.[140] The linear no-threshold model assumes all radiation doses have some carcinogenic risks without any benefits (e.g., delayed detection of life-threatening diseases and/or increased rates of invasive, high-risk procedures).

The cancer risk associated with CT scans is very small, but probably not zero.[142] Epidemiology data indicate absorption of high radiation doses (i.e., >500 mGy) by the embryo or fetus produces increased cancer risks, whereas the cancer risk from radiation doses below 100 mGy depends on the linear, no-threshold model. Extrapolation of cancer risks in this range remains controversial.[143] Stochastic effects (e.g., cancer and teratogenesis including abortion during pre-implantation) may occur below 100 mGy,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

particularly the risk of childhood cancer following prenatal radiation exposure;[144] however, no current model can accurately predict the risk associated with exposure to radiation doses of <100 mSv.

Overall Cancer Risk

The overall cancer risk varies with several factors including age at exposure, organ, dose, and dose rate. Analysis of data from the Oxford Survey of Childhood Cancers case-control study of *in utero* exposure to diagnostic X-rays demonstrated an excess risk coefficient for childhood cancer before 15 years of age.[145] The excess relative risk coefficient was ~50/Gy, whereas the excess absolute risk coefficient was ~8%/Gy. The US National Research Council's committees on the Biological Effects of Ionizing Radiations (BEIR) prepared a series of reports on the health consequences of radiation exposures based on the linear no-threshold model using data from Japanese atomic bomb survivors.[9] Figures 40.10 and 40.11 list the estimated average lifetime attributable risk of cancer for males and females, respectively, following a single 100 mSv exposure based on age of radiation exposure. The model extrapolates radiation doses below 100 mSv based on a linear slope to zero (i.e., dose/100 times the value at the age of exposure). The attributable cancer risks are higher in children than adults because of their longer life expectancy and the increased radiosensitivity of pediatric tissues. The higher estimated cancer risks in women result primarily from the additional risk of breast cancer and the relatively high lung cancer risk coefficients.

Although recent analysis of the Japanese data continues to support the no-threshold concept, data in the 0–200 mSv range suggest the possibility of a linear-quadratic dose-response model that provides lower risk estimates than the linear no-threshold model at the low radiation doses involved in medical imaging.[146] This Radiation Effects Research Foundation study of 93,000 residents of Hiroshima or Nagasaki during the atomic explosions demonstrated a statistically significant increased cancer incidence for residents with single whole-body doses of >100 mSv; the mean whole-body radiation dose of the cohort was ~200 mSv. Approximately 49,000 survivors in this cohort received estimated radiation doses of ≥5 mSv with ~32,000 receiving <100 mSv and ~2,000 >1 Sv. Below 100 mSv, the cancer incidence was not statistically different than in the unexposed population. Although formal dose-threshold analysis indicated no threshold with a zero dose being the best threshold estimate, the upper 95% confidence limit of the threshold was 150 mSv. For mortality from solid cancers at age 70 years after exposure at 30 years, the sex-averaged excess relative risk was 0.42/Gy (95% CI: 0.32–0.53/Gy) based on a linear model.

Leukemia

Several case-control studies of women and their children irradiated during the 1950s–1970s primarily in the later stages of pregnancy suggest the embryo is more sensitive to radiation-induced leukemia than adults.[147,148] In the Oxford Survey of Childhood Cancers Study, *in utero* radiation exposure from diagnostic pelvimetry ranged from 5–50 mGy. An updated analysis of the Oxford study 1953–1979 demonstrated an excess mortality from childhood leukemia at levels above previous UNSCEAR estimates (i.e., 20%/Gy vs. 7–8%/Gy);[149] However, data lacked a dose-response relationship with prenatal radiation exposure; additionally, the study suggested a relationship between maternal ingestion of antipyretics or antibiotics during pregnancy and childhood cancer. Reviews of case-control studies indicated an equivalent excess absolute leukemia risk of ~3%/Gy.[150,151] The excess relative risk (ERR) coefficient (i.e., the proportional increased leukemia-related mortality risk over the background radiation dose received by the red bone marrow) increased to a maximum excess absolute risk coefficient of ~3%/Gy 7 years after radiation exposure with a minimum latent period of 2 years.[145] The author considered these risks consistent with extrapolation of the linear no-threshold model to the Japanese atomic bomb data; however, the authors stated there was considerable uncertainty with probable overestimation of the coefficients, particularly from the unusual pattern of similar relative risks for leukemia and other common types of childhood cancer in the case-control studies. This pattern was not observed in the Japanese atomic bomb survivors or cohorts of children with postnatal radiation exposure. For radiation doses of 0.1–2 Gy received during medical procedures, the estimated ERR for leukemia ranges from ~1.9–5/Gy, whereas the EAR (excessive absolute risk) ranges from ~1–2.6/10^4 PY-Gy with little information on the effect of dose rate or age at exposure.[9]

Current data indicate the risk of developing radiation-induced carcinogenesis is lower for the fetus than for an irradiated child.[118] A study of cancer deaths in New England demonstrated excess cancer deaths in children irradiated *in utero* for diagnostic purposes with an estimated relative risk of 1.52 for leukemia compared with 1.27 for other cancers.[152] Several large prospective studies have not confirmed the association between exposure to diagnostic radiation *in utero* and an increased incidence of tumors.[95,153] Although the question of whether *in utero* irradiation (primarily pelvimetry) is a causal or associative factor for the development

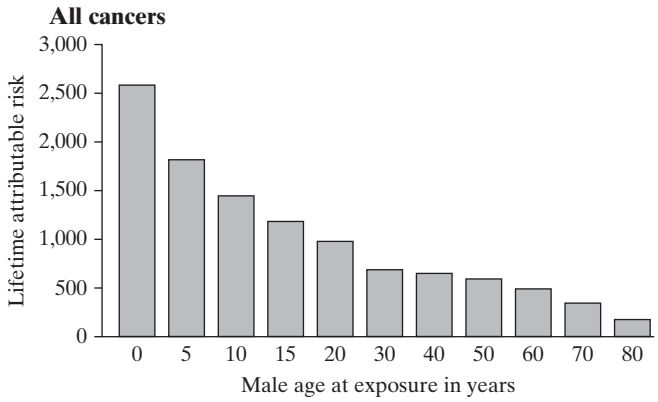

FIGURE 40.10. (*Continued*)

of leukemia remains controversial, the estimated relative risk from *in utero* exposure to 0.1–0.2 Gy in these studies consistently ranged from 1.5–2.0. *In utero* radiation doses from diagnostic radiology (i.e., <0.1 Gy) probably do not cause a substantial increase in congenital malformations, fetal demise, or *in utero* growth retardation. However, the possibility of small increases in cancer incidence or genetic hazards remains.[133,154] Although follow-up is incomplete, examination of epidemiology data from populations in Hiroshima and Nagasaki exposed to radiation *in utero* during the nuclear explosions have not detected a significant increase in childhood leukemia.[84,155,156] Japanese survivors irradiated *in utero* consist of ~800 individuals who received ≥10 mSv and an average dose of 0.25 Sv. From a public health perspective, prudence necessitates the acceptance of a causal association between *in utero* exposure to radiation and an increased risk of developing cancer; however, the potential confounding of positive studies and the inability to detect a statistically significant cancer risk in atomic bomb survivors limit conclusions regarding the nature and magnitude of the risk.

Thyroid

Although thyroid cancer is uncommon, radiation is a well-documented cause of thyroid cancer, primarily following radiation exposure in children <15 years of age. The incidence of thyroid cancer is relatively high in patients under the age of 40 years with the incidence increasing slowly with age. The linear model best describes the dose-response with little risk when exposure occurs after 20 years of age and a decreasing risk following high radiation doses used in cancer therapy.[9] The risk of thyroid cancer is 3-fold higher in women than men. Most studies of thyroid cancer involve incidence rather than mortality because the prognosis for most thyroid papillary carcinomas is good. In six case-control studies of children exposed to external radiation for benign conditions, the ERR/Gy ranges from 3/Gy in 234 children exposed for enlarged tonsils and other benign head and neck disorders[157] to 30/Gy in an Israeli study of 10,834 children exposed during the treatment of *T. capitis*.[158] The estimates for estimated excess attributable risk (EAR) in these studies vary from $0.9/10^4$ PY-Gy in the study of 14,351 Swedish children irradiated for hemangiomas[159] to $13/10^4$ PY-Gy in the *T. capitis* study.[158] In a pooled analysis of five cohort and two case-control studies, the excess relative risk per Gy (ERR/Gy) for children under 15 years of age was 7.7 (95% CI: 2.1–28.7); the excess absolute risk per 10,000 person years-Gy (EAR/10^4 PY-Gy) was 4.4 (95% CI: 1.9–10.1).[160] The attributable risk percent at 1 Gy was 88%. The studies included atomic bomb survivors, children treated for *T. capitis*, two studies of children irradiated for enlarged tonsils, infants irradiated for an enlarged thymus gland, and two case-control studies of patients with cervical cancer and childhood cancer.

Environmental Monitoring

General Population

The International Commission on Radiological Protection (ICRP) recommends an annual effective dose limit of 1 mSv exclusive of natural and medical radiation exposures.[161] The annual dose may be exceeded in any year provided the 5-year average does not exceed 1 mSv/year. The recommended annual equivalent doses for the ocular lens and the skin are 15 mSv and 50 mSv, respectively. The National Council on Radiation Protection and Measurement recommends exposure limits for the public that are ~≤10% of the occupational limit as measured by whole-body effective dose.[12]

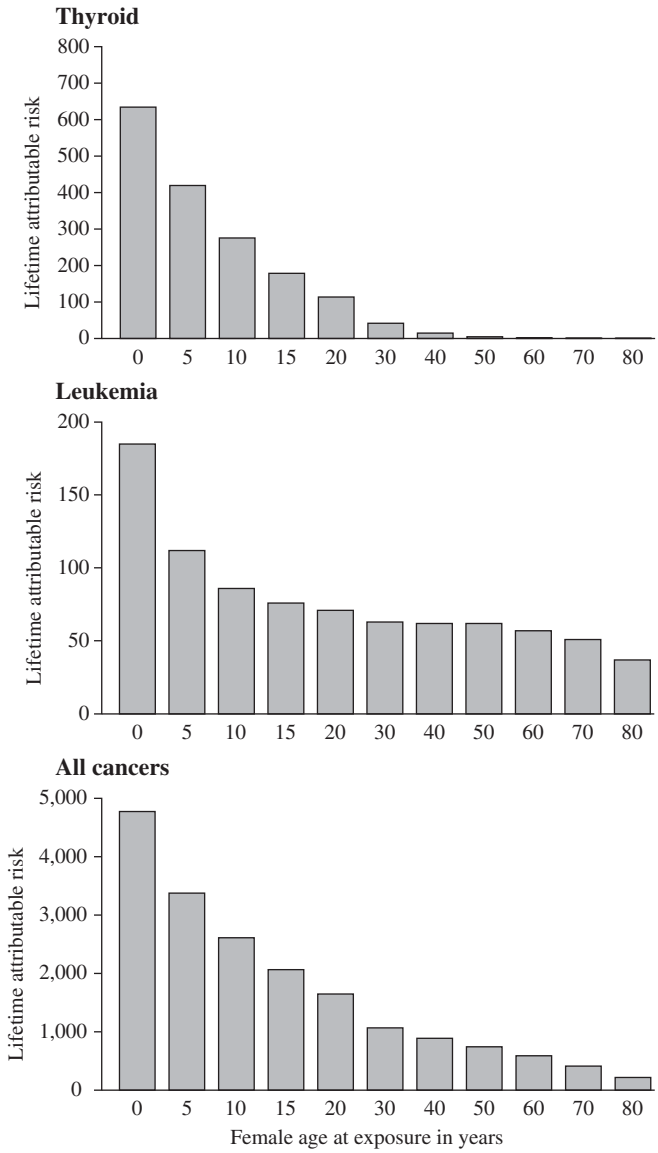

FIGURE 40.11. (*Continued*)

Patients

The decision to perform medical imaging depends on the clinical evaluation of the risks and benefits of the procedure. The radiological examination should do more good than harm, provide necessary information that usually improves the diagnosis or treatment, and produce reliable information to solve the clinical question. Examples of radiographs not routinely justified include nasal bone radiographs in children <3 years of age, cervical spine radiographs in children with torticollis in the absence of trauma, and comparison views of the opposite extremity for evaluation of a limb injury. Consideration should always be given to alternative imaging techniques that provide similar information without ionizing radiation (ultrasound, magnetic resonance imaging).

Radiological Dose Optimization

In order to deliver the lowest radiation dose necessary to achieve the required medical objective, the imaging parameters should be optimized and protective measures instituted consistent with as low as reasonably achievable (ALARA). Optimization of radiological protection includes maintaining optimum function of radiological equipment with quality control, ensuring radiological equipment and technical

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

parameters provide adequate images for the patient and the intended clinical indication, and using radiographical techniques (e.g., positioning, immobilization, field size, protective shielding) to minimize image noise.[8] Beam quantity is primarily influenced by the tube current-exposure time product (mAs), whereas tube voltage (kV) and tube filtration (mm Al) mainly determine beam quality. Reducing the size of the primary field of the X-ray beam is an important method to reduce patient and operator radiation exposure.[162] The minimum distance between the X-ray tube (collimator) and the patient is usually 30 cm to prevent the delivery of high radiation doses. Personnel assisting in the use of mobile X-rays should remain at least 6 ft from the X-ray tube, the patient, and the useful beam. Leaded gloves and aprons should be worn if holding the patient requires personnel to remain within 6 ft of the safety zone during the use of the X-ray machine. Optimization of the radiation dose also requires performance tests on equipment linked to surveys of patient radiation doses with comparisons to published diagnostic reference levels.[130]

Minimizing radiation exposure for patients and healthcare professionals involves practices that reduce exposure time, increase the distance between the radiation source and the individual, and the use of appropriate barriers (e.g., lead or tungsten/tin aprons, lead-lined barriers), particularly during CT and fluoroscopy procedures.[163] Because of the higher radiation levels with fluoroscopy and angiography, the distance from the source should always be maximized and leaded gloves and aprons should be worn during the procedure. A study of gastroenterological fluoroscopy indicated radiation doses underneath the leaded apron of pregnant technicians were similar to the radiation dose received from environmental exposure; the radiation dose did not exceed current standards.[164] For CT scans, dose reduction involves adjustment of scan parameters (pitch, mAs, kVP) to patient size, weight, and age, accepting images sufficient for the radiological diagnosis, avoiding overlapping scan regions, and restricting the region scanned to region needed to answer the clinical question.

Occupational Monitoring

Workplace

Most institutions recommend the justification of all radiation doses (i.e., sufficient benefit to exposed individual or society to offset the detriment caused) and the delivery of a radiation dose as low as reasonably achievable (ALARA) to provide the needed clinical information. The annual whole-body dose limit recommended by the International Commission on Radiological Protection (ICRP) for radiation workers in planned exposure situations is an effective dose of 20 mSv averaged over 5 years with no year exceeding 50 mSv.[161] The range of reference levels for effective dose (acute or annual) during radiological emergencies is 20–100 mSv. For the hands, feet, and skin, the recommended upper limit for the annual equivalent dose in planned exposure situations is 150 mSv, whereas the equivalent dose for the eye is 20 mSv averaged over 5 years with an upper limit of 50 mSv. Occupational and public dose limits do not include natural radiation or irradiation for medical purposes. For deterministic effects (i.e., nonmalignant), annual occupational dose limits are much higher than the annual effective doses for skin and feet (150 mSv) as well as other tissues beside the lens (500 mSv). The American Conference of Governmental Industrial Hygienists (ACGIH) adopted threshold limit values (TLV) for occupational exposure to ionizing radiation (i.e., wavelengths $<\sim$100 nm), similar to guidelines by the NCRP and ICRP.[165] The recommended effective doses combine external and internal sources exclusive of background radiation (e.g., cosmic, terrestrial, internal body sources, radon) using ICRP radiation weighting factors (W_R) and tissue weighting factors (W_T). The equivalent dose represents the sum of external and internal absorbed doses adjusted for differences in the quality of radiation by multiplying the sum by W_T. Table 40.15 lists the ACGIH guidelines for occupational exposure to ionizing radiation that are under review.

Radiation to the hand is the limiting dose for purposes of preventing excessive radiation exposure to radiologists and other medical specialties involved in interventional procedures (e.g., orthopedics, cardiologists). The skin of the fingers is the limiting organ for individual monitoring of external radiation in some medical specialties (e.g., interventional radiologists/cardiologists, nuclear medicine). In these medical environments, a wide variety of radiation field characteristics and difficulties measuring the maximum skin dose with a single detector complicate accurate dosimetry of the extremity.[166] Hemodynamic procedures usually involve high dose area product (DAP) values from the intensive use of image acquisition, particularly percutaneous transluminal coronary angioplasty. Often, the hands, legs, and eye lenses remain inadequately unshielded. Without protective measures, hand doses during angiography vary from 0.12–0.71 mSv, whereas finger doses range up to 0.84 mSv during vascular radiology procedures.[167] In a literature review in the early 1970s–middle 2000s,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 40.15. American Conference of Governmental Industrial Hygienists (ACGIH) guidelines for occupational exposure to ionizing radiation. The effective dose includes internal and external sources. The annual radiation from radon and radon daughters should be included in the calculation of the effective dose if activity concentrations in air exceed 300 Bq/m^3 after radon mitigation measures. In practice, tracking cumulative radiation doses may be difficult because of the costs and logistics. (Data from ACGIH).[165]

Exposure	Annual Guideline (mSv)
Effective dose (Stochastic effects)	
Single year[a]	50 mSv
5-Year average	20 mSv/year
Cumulative effective dose	10 mSv × age in years
Embryo/fetus effective dose	0.5 mSv/month[c]
Annual absorbed dose (Tissue reactions)	
Lens of eye	50 mSv/year
Skin, hands, feet	500 mGy/year[b]

[a] ≥18 years; for children under 18 years, the recommended limits are 1 mSv/year; [b] Annual absorbed dose of skin or extremities averaged over the most highly exposed 10 cm^2 of skin, [c] Exposure to radioiodine should be minimized or avoided in pregnant workers to avoid the risk of congenital hypothyroidism.

articles on radiation exposures to operators from diagnostic or interventional fluoroscopically guided cardiovascular procedures, the effective doses ranged from 0.00002–0.038 mSv for diagnostic catheterizations, 0.00017–0.0312 mSv for percutaneous coronary interventions, 0.00024–0.0096 mSv for ablations, and 0.00029–0.0174 mSv for pacemaker or intracardiac defibrillator implantations.[168] Measurements of radiation received by junior orthopedic staff during trauma operations indicated the radiation dose was below the 1990 ICRP guidelines (ICRP Report 60).[169,170] Considerable variation in the whole-body and organ radiation doses occurs in orthopedic staff as a result of several factors, including differences in procedures (open vs. minimally invasive), distance from the primary and secondary radiation sources, work experience (junior vs. senior surgeons), and the use of personal protective equipment (aprons, gloves, thyroid collars, eyewear). In a review of 42 articles on radiation exposure of hands, eyes, and thyroid gland in orthopedic staff, the annual cumulative dose to the hands/fingers ranged from 0.03–1.27 mSv compared with 0.06–23 mSv for the eyes/forehead and 0.07–30 mSv for the thyroid gland/neck area.[171] The average radiation dose was higher during minimally invasive procedures by the orthopedic surgeon, particularly the dominant index fingertip; all the radiation doses were below the ICRP recommendations.

Pregnancy

Once pregnancy is declared, the International Atomic Energy Agency and the International Commission on Radiological Protection recommend limiting additional fetal radiation dose to ≤1 mSv during the pregnancy.[172] This dose is the sum of the effective dose from external sources and committed effective dose from internal sources including: 1) irradiation of the embryo/fetus from mother's external exposure to radiation; 2) irradiation of the embryo/fetus from radionuclides in maternal tissues; and 3) irradiation of the newborn from radionuclides in maternal tissues. The toxicity of radionuclides depends on the radiation emitted rather than the chemical properties, except for radionuclides with extremely long half-lives. Most radiation exposures during pregnancy involve medical irradiation or air travel. In a study of diagnostic radiology workers in England, only 0.3% of the annual exposures exceeded 2 mSv with sealed-source technicians and radiotherapy theater nurses at the highest risk.[173] The exposure of medical workers to ionizing radiation is typically substantially below current recommendations; however, some areas of concern include angiography (e.g., cardiac catheterization) and C-arm fluoroscopy (hip pinning, pacemaker implants, exploration for foreign bodies).

In a postal survey of 9,208 pregnancies among 6,730 female and male radiographers, the overall risks of major congenital malformation (RR = 1.0; 95% CI: 0.9–1.2), chromosomal anomaly (RR = 1.4; 95% CI: 0.8–2.3), and cancer (RR = 1.2; 95% CI: 0.7–2.0) in offspring were not elevated based on general population rates.[174] The study suggested borderline excesses of chromosomal anomalies other than Down's syndrome in the children of female radiographers (RR = 3.9; 95% CI: 1.3–9.0; $n = 5$) and cancer in the children of male radiographers (RR = 2.7; 95% CI: 0.9–6.5, $n = 5$); however, the small numbers limit conclusions regarding causation.

TREATMENT

Preexposure

Most countries do not require dose limits for common medical imaging examinations; however, all medical radiation should be kept to the lowest level reasonably achievable (ALARA). Considerations prior to radiation exposure include reviewing the circumstances of each case, assessing the benefit of the radiographical procedure (e.g., the importance of the test to the management of the patient), determining options for alternative procedures with less or no radiation exposure, and

discussing the risks/benefits of the radiographical procedure with the patient. The possibility of pregnancy should be considered prior to the use of X-rays. The risk of genetic damage during the first month is small; therefore, no special limitations on the use of X-rays [e.g., limitation of X-rays to the first 10 days of the menstrual cycle (10-day rule)] are necessary.[175] The risks of irradiating the ovum within several weeks prior to fertilization and the embryo within the first several weeks are similar.[176]

The sensitivity of the embryo and fetus to the effects of radiation depends, in part, on the time of gestation. During the pre-implantation period, the embryo is susceptible to the lethal effects of radiation; however, the embryo is relatively insensitive to teratogenesis and growth retardation. The embryo (i.e., the first 8 weeks of gestation) is most sensitive to the teratogenic effects of radiation as it enters the period of major organogenesis. No risk of mental retardation occurs during the first 8 weeks. The peak period of susceptibility to functional abnormalities of the central nervous system occurs in the early fetal period, primarily during weeks 8–15 of gestation. Radiosensitivity of the fetus decreases during the latter part of gestation.

A woman should not be denied a medically important diagnostic X-ray to diagnose and/or treat a medical condition only on the basis of her pregnancy.[177] The physician in consultation with the radiologist may elect to cancel or perform a complete or a modified X-ray examination based on an evaluation of the risks and benefits of the examination. Modifications to the examination include the use of leaded aprons over the abdomen and pelvis, the selection of only certain views, alternative nonionizing imaging (e.g., ultrasound), and the utilization of efficient collimators. Elective and follow-up X-ray examinations should be postponed to the postnatal period; however, the immediate medical care of the mother should take priority over potential risks to the fetus.

Postexposure

Counseling a pregnant patient about the risks of diagnostic X-rays following the radiation procedure requires a careful evaluation of the timing of radiation exposure in relation to her pregnancy, type of examination, associated maternal risk factors (age, disease, gestational history), radiation dose, and her personal beliefs. Most X-rays and nuclear medicine procedures deliver <50 mGy to the fetus; therefore, the risk of congenital malformations and growth retardation is small compared with spontaneous risks. The spontaneous abortion rate during pregnancy ranges from 30–50%,[178] whereas the average risk of major malformations is ~2.75–3% and the number of children born with any malformation ranges up to 10%. Lifetime cancer risks associated with the low, *in utero* radiation doses occurring during medical imaging are primarily theoretical based on extrapolation of Japanese atomic bomb data using a linear no-threshold model that assumes all radiation causes some risk of cancer. The actual risks are controversial with current epidemiological studies containing large statistical uncertainties that do not provide consistent estimates of small radiation risks for whole-body effective doses of <100 mSv, particularly for radiation doses below 10 mSv.[141]

Contrast-Induced Nephropathy

The two main risk factors for the development of acute contrast-induced kidney injury (CI-KI) are preexisting renal disease and the volume of contrast media. Intravascular volume depletion is also an important risk factor for acute kidney injury following contrast-enhanced radiographical studies; simple hydration with saline to treat dehydration and expand intravascular volume is an established therapy to reduce the incidence of CI-KI.[179] In a prospective study of 408 patients with ST-elevation myocardial infarction receiving isoosmolar nonionic contrast medium, the use of isotonic saline (1 mL/kg/hour) during and 24 hours after the procedure reduced the incidence of CI-KI by 48% when comparing the incidence in the saline group (11%) and the group without hydration (21%).[180] Mortality and the need for dialysis also increased in the group with CI-KI. The most important measures to prevent CI-KI include adequate hydration (with or without sodium bicarbonate) along with careful monitoring of fluid balance, serum creatinine concentrations, and urine volume during the first 72 hours after contrast-enhanced radiographical studies. The ideal isotonic saline infusion rate is unclear; however, the use of 1–1.5 mL/kg/hour 3–12 hours before the study and 6–12 hours after with the goal of a urine volume of 150 mL/hour is a reasonable protocol.[181]

In addition to the use of adequate hydration prior to contrast administration as a method to minimize the risk of contrast-induced nephropathy, several pharmacological agents (e.g., *N*-acetylcysteine, statins) have been studied as part of routine preparation. However, the role of these agents in the prevention of CI-KI remains undefined. In the PRESERVE clinical trial that was terminated early, a modified intention-to-treat analysis of 4,993 patients undergoing angiography with high risk for renal complications did not demonstrate the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

benefit of 1.26% intravenous sodium bicarbonate over intravenous sodium chloride or 5 days of oral acetylcysteine over placebo based on measured outcomes.[182] The primary end point was a composite of persistent ≥50% increase in serum creatinine from baseline at 3 months, initiation of dialysis, and death with the development of contrast-induced kidney injury as a secondary end point. Although the use of statins and sodium bicarbonate may reduce the incidence of CI-KI, the use of these preventive measures does not clearly reduce overall mortality or the need for renal replacement therapy, whereas hydration *with* forced diuresis does not reduce the incidence of CI-KI.[179]

Studies on the efficacy of *N*-acetylcysteine to prevent contrast-induced nephropathy after medical imaging are inconsistent. The addition of *N*-acetylcysteine (NAC) to preprocedural protocols may provide additional benefit to the use of IV hydration;[183] however, some studies did not demonstrate an additional benefit of adding *N*-acetylcysteine to preexamination fluid boluses in the emergency department.[184] The latter study found that the hydration of the patients undergoing contrast-enhanced CT was the most important factor in reducing contrast-induced nephropathy. The contrast-induced nephropathy rate was 3.3% in patients receiving ≥1 L normal saline prior to the examination compared with 12.9% in patients receiving <1 L saline preexamination. This difference represented a 69% risk reduction (OR = 0.41, 95% CI: 0.21–0.80). Although the use of sodium bicarbonate may reduce the risk of contrast-induced nephropathy compared with hydration alone,[185] the benefit of using sodium bicarbonate in addition to IV hydration and *N*-acetylcysteine in high-risk patients remains controversial.[186] The use of these regimens probably does not cause serious adverse effects; however, other, relatively small studies of moderate to high-risk patients have not detected statistically significant difference in the development of contrast-induced nephropathy following the use of 150 mg/kg NAC in 1000 mL of 0.9% sodium chloride (NaCl), 150 mEq of sodium bicarbonate in 1000 mL of 0.9% NaCl, or 1000 mL of IV saline infusion infused at 350 mL/hour for 3 hours.[187]

RADIOTHERAPY

HISTORY

Medical application of radium to the treatment of cancer began within a few years of the discovery of radium by Pierre and Marie Curie in 1898.[188] During the first two decades of the 20th century, radium therapy became a recognized treatment for eradicating cancer. Almost all states in the United States had hospitals with radium supplies to place radioactive material inside the body near a tumor (i.e., brachytherapy) by the early 1930s.[189] The use of brachytherapy was significantly curtailed by mid-century because the use of standard protective measures (e.g., shielding, long-handled instruments) failed to reduce risks for exposed practitioners and ancillary personnel.[190] The replacement of radium and radon by lower-energy radionuclides (^{198}Au, ^{60}Co, ^{137}Cs, ^{192}Ir, ^{182}Ta) marginally improved healthcare worker safety. The development of remote techniques to insert radionuclides into previously implanted applicators (i.e., afterloading) eliminated the radioactive source from the operating and recovery rooms, allowing implantation in a well-controlled setting following optimum dose calculation and loading.[191]

EXPOSURE

Approximately one-half of cancer patients in developed countries receive radiotherapy.[192,193] Common types of therapy equipment are cobalt teletherapy equipment and linear accelerators. The former units use γ-rays emitted from a sealed source of ^{60}Co; these units are designed to provide continuous shielding from the radionuclide unless the patient is ready for therapy. In contrast to betatrons and X-ray machines that do not emit radiation unless the power is switched on, sources using ^{60}Co or ^{137}Cs are potential radiation sources at all times. Linear accelerators produce high-energy X-rays or electron beams when energized; therefore, little radiation exposure occurs unless the unit is in operation. Electron beams are effective only for shallow tumors because of their limited penetration. When linear accelerators operate above 10 MeV, neutron activation can produce some radionuclides in the patient; however, the hazard to health personnel and the patient half-lives is minimal because of the short half-lives and low energy of these radionuclides. The development of computerized control of treatment parameters and 3-dimensional (3-D) imaging allows the delivery of radiation to complex volumes of tissue that closely resemble the tumor.[194,195] The transition from conventional radiotherapy to 3-D conformal radiation therapy (3D-CRT) produces increased radiation doses to the target volume with a reduction in the volume of normal tissues receiving high radiation doses. By contrast, a change from 3D-CRT to intensity-modulated radiation therapy (IMRT) involves

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

more fields with dose-volume histograms suggesting larger volume of normal tissue receives lower radiation doses.[196] Modeling of the carcinogenic risks suggests the absolute risks of second primary malignancies associated with these two modalities are similar (2.1% and 1.7%, respectively).[197] Experimental radiotherapy applications include charged-particle radiotherapy (proton, heavy-ion) and boron neutron capture therapy. High construction costs, large size, need for specialized equipment, and availability of particle accelerators (e.g., cyclotrons, synchrotrons, linear accelerators) limit the use of these therapies for large numbers of cancer patients.[198] High-energy cyclotrons produce high-energy (14–66 MeV) neutron beams comparable with linear accelerators, but questions on efficacy, cost, and the extent of adverse reactions restrict this treatment to experimental uses (e.g., metastatic head and neck cancer, recurrent glioma).[199,200]

Brachytherapy is the branch of radiotherapy associated with the permanent or temporal placement of radioactive sources close to irradiated tissue. This technique produces the greatest risk to health personnel using medical radiation.[162] Grenz rays are ionizing radiation between UV light and X-rays (0.007–0.4 nm) on the light spectrum that possess very low energy levels in the range of 8–15 kV; these rays penetrate the first 2–3 mm of the skin with 50% of the energy absorbed in the first 0.5 mm.[201] Gustav Bucky developed the first grenz ray apparatus in 1923. This type of radiation has been used for several decades to treat benign dermatoses (e.g., hand eczema, psoriasis, allergic contact dermatitis);[202] however, basal cell and squamous cell carcinomas developed in patients receiving high skin doses (i.e., 100–293 Gy).[203,204]

CLINICAL RESPONSE

Deterministic Effects (Tissue Reactions)

The incidence and severity of deterministic effects are dose-related after the dose exceeds the threshold for the effect, typically >500 mSv.[205] Cell death and subsequent dysfunction after the exposure exceeding the threshold are characteristic of all deterministic effects except radiation-induced cataracts. The success of radiotherapy depends on the differential effect of the radiation on normal and cancerous cells. Of the 75 children of mothers exposed *in utero* to radiation doses of >1 Gy from radium therapy implanted for uterine cancer during the 1920s, 19 children developed mental retardation, microcephaly, and growth retardation. Three of these children had eye malformations (e.g., cataracts, strabismus, retinal degeneration, microphthalmia, optic atrophy).[206] Approximately 30% of cancer patients develop brain metastases with over ½ receiving whole-brain radiotherapy (WBRT). Frequently, cognitive decline occurs in patients treated with cranial radiation, particularly with WBRT).[207] Typically, the cognitive changes are late changes; however, neuropsychological testing may demonstrate abnormalities within 3–4 months post-radiation, particularly in executive function and memory.[208,209]

Carcinogenesis

Patients receiving radiotherapy develop an excess cancer incidence (i.e., 10–40% ↑RR) of second cancers in sites remote from the treatment fields, in addition to the excess incidence of sarcomas in the heavily irradiated in-field tissues.[196,210] The short life expectancy of patients receiving radiotherapy and the subsequent limited follow-up for solid tumors with latency period of >10 years complicate the determination of the incidence of second primary malignancies following radiotherapy. In a study of 104,760 1-year survivors of cervical cancer, the standardized incidence ratio (SIR) of second primarily malignancies in heavily irradiated sites (>3 Gy) remained elevated >40 years after exposure; the sites included colon, rectum/anus, urinary bladder, ovary, and female genitalia.[211] Sites irradiated with ≤3 Gy did not demonstrate a statistically significant elevation of second tumors at these sites. Current estimates suggest these tumors may occur in up to 20% of radiotherapy patients receiving fractionated radiation doses >2 Gy.[212] All second primary malignancies in these patients do not result from radiation because: 1) sporadic cancer occurs in any cohort; 2) genetic factors increase the risk of cancer in these patients; 3) exogenous factors (e.g., alcohol, tobacco, obesity) contribute to tumor induction; and 4) enhanced medical surveillance increases the detection of low-grade malignancies frequently undetected in the general population. The incidence of second primary tumors varies with several factors, including the tissue and organs, patient age at time of treatment, hereditary factors, dose, dose rate/fractionation, dose distribution, and size of the irradiated volume. The most sensitive organs to the development of secondary tumors after radiotherapy are the thyroid, breast, leukemia (excluding chronic lymphocytic leukemia), bone, central nervous system, basal cell skin carcinoma, and lung (especially in smokers).[213] Preliminary data suggest these tumors occur in a dose-response relationship, primarily after the absorption of radiation doses of >2 Gy as fractionated irradiation. Threshold doses for thyroid and breast cancers may be as low as 100 mGy

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. in children and 500 mGy for lung tumors in smoking adults. The risk of brain tumors following irradiation in adults is relatively low.[214] Important follow-up studies of patients treated with radiotherapy for nonmalignant diseases include ankylosing spondylitis, arthritis, benign gynecological disease, hemangiomas, hyperthyroidism, peptic ulcer, polycythemia, postpartum mastitis, thymic hyperplasia, *T. capitis*, and tuberculosis.

Leukemia

Radiation-induced leukemia may manifest after a few years with an elevated risk persisting up to 15–25 years for acute myeloid and lymphocytic leukemia but not for chronic myeloid leukemia.[215] The latency period depends on leukemia subtype (e.g., chronic myelocytic leukemia has the shortest mean latency of ~5 years) and age at exposure (i.e., children are 2-fold more sensitive with shorter latencies than adults).[216] In an Israeli study of 10,834 children treated for *T. capitis* and followed for an average of 26 years, the relative risk for all leukemia was marginally statistically significant (RR = 2.3, 95% CI: 1.0–5.6; $n = 14$) with mortality increasing for three main subtypes at that time (acute myeloid leukemia, acute lymphocytic leukemia, chronic myeloid leukemia); no cases of chronic lymphocytic leukemia were reported.[217] The estimated radiation dose over 5 days to the upper brain was 121–139 rad (1.21–1.39 Gy) and 400 rad (4 Gy) to the bone marrow in the skull. The number of leukemia cases was too small to calculate the relative risks for the three leukemia subtypes. A smaller study of 2,224 New York children treated with scalp radiation for *T. capitis* following a median of 39 years did not detect an elevated mortality in the treated group; however, the standardized incidence ratio (SIR) was elevated for leukemia (SIR = 3.2; 95% CI: 1.5–6.1; $n = 8$).[218] A UK study of 14,106 ankylosing spondylitis patients demonstrated 3-fold increased mortality from leukemia when compared with the general UK population.[219] The risk of death from leukemia peaked 10–12.4 years after the single radiation treatment for ankylosing spondylitis. The estimated mean radiation dose for the active bone marrow in these patients was 3.83 ± 2.20 Gy with a range of 0–13.10 Gy using Monte Carlo methods.[220] Follow-up studies of women receiving radiotherapy for cervical cancer indicate an increased risk of radiosensitive leukemia subtypes.[210] In women receiving several Gy to the cervix for cervical cancer, the relative risk of leukemia increased 2-fold (RR = 2.0; 90% CI: 1.0–4.2); the radiation doses in this study did not increase the risk of chronic lymphocytic leukemia (RR = 1.03; $n = 52$).[221] The risk of leukemia after radiotherapy for cervical cancer increased with increasing mean bone marrow doses to 4 Gy while decreasing with higher doses. The risk of leukemia increased beginning 2–5 years after radiotherapy of the cervix with the peak observed/expected ratio peaking 10–15 years after radiotherapy.[215]

Thyroid

The thyroid gland in children is particularly radiosensitive with relatively high risk coefficients and convincing evidence for increased risk above ~1.1 Gy. The relative risk of thyroid cancer is highest for children <5 years of age, with the risk decreasing 2-fold between 5–10 years and 5-fold for adolescents.[216] Adults over 40 years of age have a low risk of developing thyroid cancer after radiotherapy. In a pooled analysis of five cohort studies (atomic bomb survivors, children treated for *T. capitis* and enlarged tonsils, infants irradiated for an enlarged thymus gland) and two case-control studies (cervical cancer, childhood cancer), the pooled excess relative risk per Gy (ERR/Gy) for children exposed before the age of 15 years was 7.7 (95% CI: 2.1–28.7).[160] The risk appeared linear to 100 mGy with doses mostly <10 Gy; however, little risk occurred when the radiation exposure occurred after 20 years of age. More thyroid cancer cases than expected occurred in the New York study on children irradiated for *T. capitis*, but the difference did not reach statistical significance.[218] The incidence of thyroid cancer was elevated in the study of 2,657 US infants irradiated during infancy for an enlarged thymus and followed for a mean of 37 years; 37 pathologically confirmed thyroid cancers occurred in the irradiated group vs. 5 in sibling controls.[222] After adjustment for sex and attained age, the relative risk for thyroid cancer in the irradiated group was 18.2 (90% CI: 8.5–43) compared with sibling controls. The estimated thyroid doses ranged from 0.03 to over 10 Gy with 62% receiving >0.5 Gy. The risk ratio declined with time; however, the risk remained elevated 45 years after irradiation. In a review of pooled data from 12 studies of thyroid cancer patients exposed to radiation before the age of 20 years, the relative risks increased supra-linearly through 2–4 Gy, flattened 10–30 Gy, and subsequently declined while remaining significantly elevated above 50 Gy.[223] The ERR/Gy varied from 1.4–4.5 with the upper bound similar to acute childhood Japanese exposures and previous pooled analyses of thyroid cancer studies.

Breast

Women aged 15–25 years are the most sensitive to radiation-induced breast cancer, whereas women over 40 years of age have little risk of radiation-induced

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

breast cancer. Consequently, the breast cancer incidence rates after radiation exposure vary with the cohort studied. In an analysis of breast cancer rates in eight large cohorts with and without primary tumors, no single model described the breast cancer rates following radiation doses varying from protracted low-dose-rate exposures of 0.1–5 Gy (two Swedish skin hemangioma cohorts) to single or few high-dose-rate exposures of >5 Gy (US infants with thymic enlargement, Japanese atomic bomb survivors, Swedish benign breast disease patients, US acute postpartum mastitis patients) and highly fractionated high-dose-rate exposures (US tuberculosis cohorts).[224] The excess relative risk per unit dose was four times lower in the tuberculosis or thymus cohorts than in Japanese atomic bomb survivors, reflecting in part the low breast cancer background rates in Japanese women. In a study of 1,201 women irradiated during infancy for an enlarged thymus gland and their 2,469 nonirradiated sisters (controls), the adjusted rate ratio for breast cancer was 3.6 (95% CI: 1.8–7.3; $n = 22$).[225] The mean follow-up for this cohort was 36 years with the first case of breast cancer in the irradiated group occurring 28 years after irradiation. In a systematic review of three studies of the occurrence of breast cancer after radiotherapy for a primary cancer, the ERR/Gy varied from 0.13–0.27; these values were 5–16-fold lower than the risk for similar age at exposure and attained age in studies of lower doses,[224] primarily in studies without primary malignancies.[226] An important confounder in these risk estimates is ablation of the ovaries with doses exceeding 5 Gy and the subsequent suppression of hormonal stimulation of the breast along with the cell death associated with high radiation doses during radiotherapy. In a case-control study of >150,000 women irradiated for invasive cancer of the uterine cervix, the risk of breast cancer was not increased; the estimated average radiation dose was 300 mGy.[227] A confounding factor was the large number of women over 35 years of age and the decreasing susceptibility to breast cancer with increased age of exposure.

Brain

A systemic review of eight cohort studies including therapeutic radiation in children and the Life Span Study of Japanese atomic bomb survivors reported stronger association of ionizing radiation with meningiomas than gliomas; however, the strength of the association varied substantially between studies.[228] The overall summary ERR (excessive relative risk) for meningiomas was statistically insignificant (ERR = 1.81, 95% CI: -0.51 to 4.15, $n = 4$ studies, $I^2 = 44.8\%$, $P_{\text{heterogeneity}} = 0.142$). The authors did not calculate a summary ERR for gliomas. Follow-up studies of Israeli children irradiated for *T. capitis* infections during the 1950s first demonstrated an increased brain cancer risk after radiotherapy.[229] In a retrospective cohort study of 10,834 children with a mean age at irradiation of 7.1 ± 3.1 years (range, 1–15 years), the estimated median radiation dose was 1.38 Gy (95% CI: 0.98–6.0 Gy).[230] The estimated excessive relative risk per Gy (EER/Gy) after a median follow-up of 40 years was 4.63 (95% CI: 2.43–9.12, $n = 67$ exposed) for benign meningiomas and 1.98 (95% CI: 0.73–4.69, $n = 31$ exposed) for malignant brain tumors using a combination of unexposed, matched population, and sibling controls. The RR for meningiomas was 9.5 (95% CI: 3.5–25.7) and 2.6 (95% CI: 0.8–8.6) for gliomas; however, the wide confidence intervals and lack of statistical significance for gliomas suggest the estimates are imprecise.

Reproductive Abnormalities

Current medical evidence does not support an increased incidence of malformations, stillbirths, neonatal deaths, or cytogenetic markers of heritable genetic mutations in the offspring of women irradiated for cancer as children, adolescents, or young adults. In a case–cohort study of 472 Danish survivors of childhood and adolescent cancer and their 1,037 pregnancies, the risk of genetic disease in children of irradiated and nonirradiated survivors was similar (RR = 1.02; 95% CI: 0.59–1.44; $P = 0.94$).[231] The risk of congenital malformations ($n = 159$), stillbirths ($n = 7$), and neonatal deaths ($n = 9$) was not elevated in the offspring of female survivors receiving abdominopelvic radiation ($P = 0.7$) or children of mothers receiving mean uterine doses of 3.5 Gy up to a maximum of 100 Gy (RR = 2.3; 95% CI: 0.95–5.56). A retrospective cohort analysis of data from the US Childhood Cancer Survivor Study did not detect an increased risk of stillbirth and neonatal death among the offspring of 1,148 male survivors of childhood cancer.[232] The adjusted relative risk was 0.8 (95% CI: 0.4–1.6); the mean dose to the testes in 16 men was 0.53 ± 1.40 Gy. For girls irradiated before menarche, uterine and ovarian doses in the range of 1.00–2.49 Gy significantly increased the risk of stillbirth or neonatal death (RR = 4.7; 95% CI: 1.2–19.0; $n = 3$). The authors attributed the increased risk to radiation-induced uterine damage; however, the wide confidence intervals suggest imprecise estimates.

HEALTH SURVEILLANCE

A well-equipped laboratory with appropriate handling equipment and sufficient shielding is necessary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. to minimize the exposure of personnel to radiation during brachytherapy. Afterloading techniques allow the preparation of the patient and the insertion of applicators before the introduction of the radioactive source. Treatment rooms should contain alarms to indicate high radiation levels and to alert personnel to entry into the room during the operation. Radiation levels in the control room should be checked to ensure radiation in the control room remains below 25 μSv/hour.[162] Operators should stay in the control room during use of the equipment.

Chapter 41

INTERNAL CONTAMINATION AND INDUSTRIAL, MEDICAL AND MILITARY RADIONUCLIDES

BACKGROUND

PHYSICAL PROPERTIES

Radionuclides are unstable atoms that spontaneously disintegrate while emitting ionizing radiation. Incorporation of radionuclides into the body following inhalation, ingestion, or absorption into wounds causes internal contamination. Deposition of these radionuclides exposes the tissues and organs to ionizing radiation primarily by the release of α- particles (helium nuclei), β-particles (electrons), positrons, Auger electrons, Coster–Kronig electrons (i.e., an Auger transition, when an electron from a higher subshell of the same shell replaces a vacant electron in a lower subshell), or photons (γ-rays). The same units and principles of dose-response apply to internal contamination and external radiation. The development of stochastic and deterministic effects following internal contamination depends on the absorbed dose (MeV/g) delivered to a specific organ.

Radioactivity

Radioactivity is an exposure measure related to internal dose. The actual relationship of radioactivity to dose depends on several factors including the mode of decay (α-, β-, γ-), energy of decay, physical half-life, and kinetics of the radionuclide in the body. The measure of radionuclide decay is activity; this transformation produces particles and photons capable of interacting with tissue and potentially causing DNA damage. The SI unit of activity is the *becquerel*; this unit is equivalent to 1 transformation/second. The *curie* is the traditional unit for activity; this unit is equivalent to 3.7×10^{10} transformations/second, as listed in Table 41.1.

Pure emitter radionuclides release either α- or β-particles; the subsequent decay product is a stable isotope; however, human exposure to pure emitters is rare. Because most common radionuclides emit γ-rays as well as α- and β-particles, the number of nucleus disintegrations per unit time is not necessarily equal to the number of particles emitted from the radionuclide. The amount of radioactivity released by nuclear operations varies from the mega (10^6) becquerel range for laboratory tracers to the giga-giga (10^{18}) becquerel range for nuclear reactor cores.

Dose and Dose Rate

The absorbed radiation dose in gray (Gy) represents the energy in joules deposited per kilogram of tissue. The equivalent dose in sieverts (Sv) is the absorbed dose (Gy) adjusted for the relative biological effects of each type of ionizing radiation emitted using the radiation weighting factor (Q, also known as quality factor) listed in Table 41.2. The committed equivalent dose reflects the amount of radiation over an expected lifetime of 50 years (for an adult) or 70 years (for a child) received by an organ following the intake of radioactive material. This value is multiplied by a tissue weighting factor (Table 41.3) to adjust the amount of radiation received by that tissue in relation to the total dose assuming uniform body irradiation. The committed effective dose

TABLE 41.1. SI conversion units.

SI Unit	Traditional Units	Conversion Factors
Gray (Gy)	Rad	1 Gy = 100 rad
Sievert (Sv)	Rem	1 Sv = 100 rem
Becquerel (Bq)	Curie (Ci)	1 Bq = 2.702702702703 $\times 10^{-11}$ Ci

TABLE 41.2. Radiation weighting factors. In 2007, ICRP published a new set of radiation weighting factors (ICRP 103); however, the ICRP 60 guidelines remain the legal standards in Europe. The main difference between the two guidelines results from the use of mortality data modified for life lost by ICRP 60 guidelines, whereas ICRP 103 guidelines use incidence data rather than mortality data. The W_R for neutrons in ICRP 60 is a step function compared with a continuous function in ICRP 103 as defined by Equation 41.1. (Data from ICRP 60 and ICRP 103)

Radiation Type	Radiation Weighting Factor (W_R)
Photons, all energies	1
Electrons, myons, all energies	1
Protons and charged pions	2
α-particles, fission fragments, heavy ions	20
β-Particles	1
Neutrons	See Equation 41.1

is the sum of the products of the committed organ equivalent doses and the appropriate weighting factor.

Neutron radiation weighting factor (W_R) is a continuous function defined by Equation 41.1, which varies with the MeV (E_n).

$$W_R = 2.5+18.2e^{-[\ln(E_n)]^2/6} \quad \text{for } E_n<1 \text{ MeV}$$
$$W_R = 5.0+17.0e^{-[\ln(2E_n)]^2/6} \quad \text{for } 1 \text{ MeV} \leqslant E_n \leqslant 50 \text{ MeV}$$
$$W_R = 2.5+3.25e^{-[\ln(0.04E_n)]^2/6} \quad \text{for } E_n>50 \text{ MeV} \qquad \text{(Equation 41.1)}$$

Beta Emitters

In a medium, the average linear rate of energy loss (MeV/cm) of a heavily charged particle (e.g., α or β) is the stopping power. This value represents the retarding force acting on charged particles that results from the interaction of the particle with matter and causes loss of particle energy. There is little practical difference between stopping power and linear energy transfer (also known as restricted stopping power). Stopping power usually describes the total energy lost by the charged particle, whereas LET typically describes the energy lost by the charged particle from local absorption while traveling through the medium. Both linear energy transfer (LET, typically keV/μm in water) and stopping power are closely associated with radiation dose and biological effectiveness of the specific particle. High-energy β-particles lose ~2 MeV of energy per cm of tissue. As an approximation, 100 high-energy β-particles/cm/second = 0.1 Sv/hour. This dose rate increases for lower-energy β-particles because the rate of energy loss increases.

TABLE 41.3. Tissue weighting factors (W_T). In 2007, ICRP published a new set of tissue weighting factors; however, the ICRP 60 guidelines remain the legal standards in Europe. (Data from ICRP 60 and ICRP 103)

Tissue	Tissue Weighting Factor (W_T)	Contribution to Total W_T
Bone-marrow (red), colon, lung, stomach, breast	0.12	0.60
Remaining tissues: adrenals, extra thoracic (ET) region, gall bladder, heart, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate (♂), small intestine, spleen, thymus, uterus/cervix (♀)	0.12	0.12
Gonads	0.08	0.08
Bladder, esophagus, liver, thyroid	0.04	0.16
Bone surface, brain, salivary glands, skin	0.01	0.04
	Total	1.00

Mass stopping power (MeV/cm^2/g) of the medium is the stopping power (MeV/cm) divided by the density (g/cm^2) of the medium. This value expresses the average rate of energy loss by a charged particle where the distance is measured as an aerial density (g/cm^2). In contrast to the stopping power, the mass stopping power of a gas does not depend on pressure because the density compensates for the pressure. In general, heavy atoms are less efficient than lighter atoms at slowing heavy charged particles because most of their electrons are too tightly bound in their inner shell to efficiently absorb energy.

The dose rate at a distance from a point source of radiation decreases with the square of the distance (the inverse square law) at a minimum. When the radiation traverses a medium (e.g., air or tissue) rather than a vacuum, the dose rate decreases even more with increasing distance from the source.

Gamma Rays

The exposure rate from a point source for γ-rays with energies between 0.07 and 4 MeV is approximately proportional to the rate of γ-ray emissions from the source. Their energy and exposure rate are inversely

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

proportional to the square of the distance.

$$\text{Exposure Rate (mR/hour)} = (5{,}000 \times A \times E \times n)/d^2 \quad \text{(Equation 41.2)}$$

where

A = activity of source (mCi),
E = photon energy (MeV),
n = number of photons of energy E per disintegration,
d = distance (cm).

Because the relative biological effectiveness of γ-rays (and β-particles) is 1, the numerical value of the exposure rate is equivalent to the absorbed dose rate and the dose equivalent rate. The gray is related to the rad as fractions are to percentages (i.e., 1 Gy = 100 rad).

EXPOSURE

Although over 8,000 isotopes exist, only ~15 radionuclides are medically important. Sources for these isotopes include universities and medical settings (^{252}Cf, ^{14}C, ^{60}Co, ^{3}H, ^{125}I, ^{131}I, ^{32}P), industry (^{137}Cs, ^{60}Co, ^{192}Ir), and military/nuclear power uses (^{241}Am, ^{3}H, ^{239}Pu, ^{235}U). Internal contamination with radionuclides involves inadvertent radiation exposure from radioactive sources in industrial (e.g., materials testing, sterilization) and medical (e.g., theft of abandoned ^{137}Cs source in Goiania, Brazil) settings. Less commonly, these incidents occur during transportation accidents and rarely nuclear power malfunctions (e.g., Chernobyl, Fukushima) or intentional contamination (e.g., ^{210}Po poisoning of Alexander Litvinenko). Major radionuclide sources include the following isotopes: inhalation of ^{222}Rn, deposition of long- (^{40}K, uranium isotopes, thorium-232) and short-lived (^{226}Ra, ^{210}Pb, ^{210}Po) primordial isotopes, decay products of cosmic origin, and anthropogenic release of radionuclides ^{90}Sr, ^{137}Cs, ^{131}I, plutonium isotopes, ^{192}Ir, ^{241}Am, ^{106}Ru).[1] Tobacco smoke contains ^{210}Pb and ^{210}Po. Radon-222 accounts for ~50–80% of the background radiation dose. The average exposure to radionuclides from global fallout of fission products and waste from the uranium-plutonium fuel cycle (^{137}Cs, ^{134}Cs, ^{90}Sr, ^{242}Cu, ^{241}Am, ^{239}Pu, ^{241}Pu) is relatively small (<1%) compared with natural background radiation.

Natural Sources

The three main types of emission from radioactive substances are α-particles, β-particles, and γ-rays. These radiation types demonstrate different energy ranges, relative biological effectiveness, and effective distance. The body contains a background radionuclide level from the incorporation of naturally occurring and man-made radioisotopes in the air, food, and water. Life on earth evolved to coexist with this constant background radiation. The main source of radioactivity in the body is potassium-40 (^{40}K); the natural abundance of this radionuclide is 0.012%. Hence, the average 70 kg person contains 0.0169 g ^{40}K resulting in an annual absorbed dose of 0.16 mGy of β-radiation and 0.0.02 mGy of γ-radiation.[2] This dose amounts to ~0.175 mSv/year, which is relatively small compared to the total background dose of natural radiation.[1]

The other major radionuclide in the body is ^{14}C. The atmosphere constantly produces this radionuclide from the interaction of cosmic rays with nitrogen; however, the amount of radiation produced by internal doses of ^{14}C is ~18 times less than that of ^{40}K because ^{14}C emits β-particles with low energy levels. Other radionuclides include the α-emitters ^{210}Po, ^{226}Ra, and ^{90}Sr. These radionuclides deposit primarily in bones. The lung is the organ receiving the highest exposure to natural radionuclides principally in the form of α-particles from ^{222}Rn and ^{220}Rn (also known as thoron).

Cosmic Radionuclides

In contrast to the terrestrial radiation from primordial radionuclides, cosmic radionuclides form continuously from the bombardment of the atmosphere by cosmic radiation. This radiation produces radionuclides by a variety of reactions with atoms in the atmosphere including spallation and neutron activation. Spallation produces many hadrons (e.g., mostly neutrons) and atomic fragments following the interaction of light particles (e.g., proton, neutron, light nuclei) with high kinetic energy up to several GeV and a heavy nucleus. The latter reaction involves the excitation of atoms by the capture of neutrons and the subsequent emission of γ-rays, α- and β-particles, and neutrons. The most common radionuclides formed by cosmic rays are ^{14}C, ^{3}H, ^{22}Na, and ^{7}Be. The highest absorbed dose of cosmic radionuclides results from the ingestion of ^{14}C and, to a much lesser extent, ^{7}Be and tritium (H-3, 1 proton, and 2 neutrons). The very uncommon latter isotope is the only radioactive hydrogen isotope with a natural abundance of one trillionth of a percent.

Primordial Radionuclides

Terrestrial radiation results from radionuclides deposited during the formation of the earth. There are several dozen primordial radionuclides with radioactive

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

half-lives equivalent to the estimated age of the earth. Primordial radionuclides are classified as: 1) **series radionuclides** (e.g., ^{238}U, ^{235}U, ^{232}Th), and 2) **nonseries radionuclides** (e.g., ^{40}K, ^{87}Rb). The former series decays by progressively forming several radionuclides to reach a stable lead isotope, whereas the latter series decays directly to a stable nuclide. The original source of these primordial radionuclides is the earth's crust or the underlying plastic mantle; transfer to the hydrosphere or the atmosphere allows absorption of these radionuclides via ingestion or inhalation. The amounts of radionuclides in the environment vary with location; unusually high radionuclide concentrations exist in old mining areas (Grand Junction, Colorado; Butte, Montana; Uravan, Colorado); major phosphate rock deposits in Florida; and the Reading Prong (geological formation extending from northeastern Pennsylvania to New Jersey and southeastern New York).

External Sources

The major sources of background radiation for the general population are radionuclides (e.g., ^{40}K, radioactive decay chain of ^{238}U and ^{232}Th) in rocks and soil near the earth's surface. ^{40}K emits β- and γ-radiation; therefore, this radionuclide can be both an internal and external source of radiation (γ-rays can penetrate from outside the body), whereas ^{87}Rb is primarily an internal radiation source (i.e., nonpenetrating β-emitter). Exposure to background radiation doses occurs outdoors from radionuclides in the soil, whereas most indoor irradiation results from inhaled radon daughters.[3] The amount of radioactivity in the soil does not vary substantially between different locations, except in a few areas (e.g., phosphate deposits from mining in Florida).

Internal Sources

^{40}K is the most important source of internal radiation, despite the relatively scarce distribution of this isotope in the earth's crust. The dissemination of ^{40}K in the food chain does not influence the amount of ^{40}K in the body because of hemostatic controls on potassium in the body. Rubidium is an alkali metal that is kinetically similar to potassium in the body; however, rubidium concentrations are much smaller than potassium. Consequently, the specific activity of ^{87}Rb is much lower than ^{40}K. Relatively large ingestions of terrestrial radionuclides occur in Eskimo and Indian populations of northwestern Canada and Alaska, where the lichen-reindeer-human food chain produces high ^{210}Pb and ^{210}Po concentrations in the diet.[3] The log-normal distribution of indoor radon concentrations creates substantial variation in the amount of inhaled radioactivity from radon daughters.

Radiopharmaceuticals

Radionuclides are the source of radioactive compounds used in radiotherapy and in diagnostic testing. The source of these radioactive compounds may be sealed (e.g., accelerators) or unsealed (e.g., radiopharmaceuticals). Table 41.4 lists the physical characteristics of radiopharmaceuticals.

Radiopharmaceuticals are present in unsealed sources in liquid, particulate, or gaseous forms that can be incorporated into the body. Only a few radionuclide-emitting α-particles are attractive diagnostic or therapeutic agents, in part because these particles are difficult to detect and measure. Radionuclides that emit β-particles are used almost exclusively in radionuclide therapy. The range of high-energy β-particles is usually greater than α-particles with sparse ionization producing low linear energy transfer (LET). The primary sources of β-emitting radionuclides are neutron activation of radioisotopes in nuclear reactors with a few radionuclides produced in charged-particle accelerators. The half-lives of radionuclides used in radiotherapy are short and average ~10 days.[5]

γ-Ray-emitting radionuclides are the most common source of radiation from radiopharmaceuticals used in medical applications; however, γ-rays increase the radiation delivered to the whole body with minimal radiation deposition in the target organ and increased exposure to medical personnel. γ-Ray-emitting radionuclides are useful for scintigraphic imaging for pharmacokinetics and dosimetry studies. Generally, γ-ray emissions from radiopharmaceuticals are relatively low energy with photons in the energy range of 75–250 keV.[6] The stable isotope tracers (deuterium or ^{2}H, ^{13}C, ^{15}N, ^{18}O) used in biomedical experimentation and diagnostic procedures do not emit ionizing radiation; therefore, they do not represent a radiation hazard.[7] Adverse effects from the administration of single doses of <250 g $^{2}H_2O$ have been limited to severe, transitory episodes of vertigo that probably result from alterations in the specific gravity of vestibular fluid.[8]

Medical Imaging

Most medical diagnostic radionuclides are single photon emitters (i.e., γ-rays with energies 80–360 keV) or positron emitters.[9] Positron emitters release positrons that react with electrons via antimatter annihilation to liberate two γ-rays of 511 keV. These two photons

TABLE 41.4. Physical characteristics of the most common diagnostic and therapeutic radionuclides. Beta minus (β^-) decay involves the emission of an electron and the transformation of a neutron to a proton. Because the number of protons in an element determines the element, this process produces a different element. (Data from the United Nations Scientific Committee on the Effects of Atomic Radiation, UNSCEAR).[4]

Radionuclide	γ-Energy (keV)	Half-Life	Radiation Type
^{3}H	—	12.3 years	β-particles
^{11}C	511	20.3 minutes	Positron
^{14}C	—	5,730 years	β-particles
^{13}N	511	10 minutes	
^{15}O	511	2.06 minutes	
^{18}F	511	109.8 minutes	
^{32}P	—	14.3 days	β-particles
^{51}Cr	322	27.8 days	
^{57}Co	122, 136	271 days	
^{67}Ga	92, 184, 296, 388	3.2 days	
^{75}Se	121, 136, 265, 280, 401	120 days	
^{89}Sr	—	51 days	β-particles
^{90}Y	—	64 hours	β-particles
^{99m}Tc	140	6.02 hours	
^{111}In	173, 247	2.8 days	Auger electron
^{123}I	159	13 hours	
^{131}I	284, 364, 637	8.05 days	High-energy photons, many β-particles
^{133}Xe	81	5.3 days	β^- decay
^{153}Sm	70, 103	47 hours	β^- decay
^{165}Dy	95	2.3 hours	β^- decay
^{186}Re	137	91 hours	β^- decay
^{198}Au	412	2.7 days	β^- decay
^{201}Tl	135, 167	73 hours	
^{211}At	—	7.2 hours	α-particles

travel in opposite directions. Scintillation crystals in γ-cameras transform incoming γ-rays into photons of light that convert to electronic signals. This type of diagnostic study is called *scintigraphy*; in contrast to radiography and computed tomography, scintigraphy detects radiation emitted from **within** the patient. *Single photon emission computed tomography* (SPECT) involves a dedicated computer producing tomographic maps of γ-rays emitted directly from internal radionuclides. *Positron emission tomography* (PET) maps the anatomic emission source of the paired γ-photons generated by positron–electron annihilation occurring with the patient following administration of a positron-emitting radionuclide (e.g., tracer ^{18}F-fluorodeoxyglucose, FDG). In contrast to X-rays, CT, and MRI imaging techniques that provide details of normal and abnormal anatomy, SPECT and PET scans supply information on biochemical, metabolic, and functional changes in the body using 3-D color images; these techniques allow quantification of physiological parameters (blood flow, enzymatic activity, metabolism, protein density) *in vivo*. However, these methods do not usually provide the spatial resolution for adequate anatomical localization of the abnormalities; consequently, combined techniques (e.g., PET/MR, PET/CT) are necessary to provide precise anatomical lesion localization.[10] PET scans are clinical tools for probing biochemical pathways using short-lived tracers of carbon, oxygen, nitrogen, and fluoride created by cyclotrons to diagnose various diseases with local metabolic abnormalities (e.g., cancer, dementia, cardiac disease).[11,12]

SPECT scans are less expensive than PET scans; however, the latter is probably a more accurate imaging method.[13] Compared with plain radiography, SPECT scans provide a direct measure of function (e.g., cerebral

TABLE 41.5. The United States Food and Drug Administration (USFDA) approved radiopharmaceutical for diagnostic imaging and radiotherapy.

Radiopharmaceutical	Indication
^{11}C-choline	PET imaging of prostate for cancer recurrence
^{14}C-urea	Diagnosis of *Helicobacter pylori* infection by detection of gastric urase
^{18}F-florbetaben	PET imaging of β-amyloid plaque density in brains of patients with cognitive decline
^{18}F-florbetapir	β-amyloid PET brain imaging for the presence of Alzheimer's disease
^{18}F sodium fluoride	PET bone imaging for altered bone formation
^{18}F-fludeoxyglucose (FDG)	PET imaging for evaluating cancer (abnormal glucose metabolism), cardiomyopathies, and seizures (abnormal glucose metabolism in epileptic foci)
^{18}F-flutemetamol	β-amyloid PET brain imaging for the presence of Alzheimer's disease
^{67}Gallium citrate	Evaluation of rapidly dividing cells present in bronchogenic carcinoma, Hodgkin's disease, lymphoma, and acute inflammatory lesions
^{111}Indium capromab pendetide	Imaging of prostate cancer to detect pelvic metastasis
^{111}Indium chloride, ^{111}Indium oxyquinoline	Radiolabeling for *in vivo* diagnostic imaging procedures
^{111}Indium pentetate	Radionuclide cisternography imaging
^{111}Indium pentetreotide	Scintigraphic imaging of neuroendocrine tumors with somatostatin receptors
^{123}Iodine iobenguane	Detection of pheochromocytomas and neuroblastomas; evaluation of cardiac size and failure
^{123}Iodine ioflupane	SPECT brain imaging to evaluate striatal dopamine transporter function and the presence of Parkinson's disease
^{123}Iodine sodium iodide	Thyroid morphology and function
^{125}Iodine-human serum albumin	Estimation of plasma and total blood volume
^{125}Iodine iothalamate	Estimation of glomerular filtration rate
^{131}Iodine-human serum albumin	Evaluation of cardiac output/circulation times, delineation of heart/great vessels, localization of placenta, detection of cerebral tumors
^{131}Iodine-sodium iodide	Evaluation of thyroid function/tumors, treatment of thyroid carcinomas
^{99}Molybdenum generator	Preparation of ^{99m}Tc sodium pertechnetate
^{13}Nitrogen ammonia	PET myocardial imaging for evaluation of coronary artery disease
^{223}Radium dichloride	Treatment of castration-resistant prostate cancer
^{82}Rubidium chloride	Myocardial PET imaging of suspected myocardial infarction
^{153}Samarium-lexidronam	Treatment of bone pain from metastatic osteoblastic bone tumors
^{89}Strontium chloride	Treatment of bone pain from metastatic osteoblastic bone tumors
^{99m}Technetium bicisate	SPECT imaging of suspected stroke
^{99m}Technetium disofenin	Evaluation of suspected acute cholecystitis
^{99m}Technetium exametazime	Detection of altered cerebral blood flow, localization of abdominal infection/inflammatory bowel disease
^{99m}Technetium-macroaggregated albumin	Evaluation of pulmonary perfusion
^{99m}Technetium-mebrofenin	Hepatobiliary imaging
^{99m}Technetium-medronate	Detection of abnormal bone formation
^{99m}Technetium-mertiatide	Evaluation of renal function
^{99m}Technetium-oxidronate	Detection of abnormal bone formation
^{99m}Technetium-pentetate	Brain imaging and kidney perfusion/function
^{99m}Technetium-pyrophosphate	Detection of abnormal bone formation, myocardial infarction, gastrointestinal bleeding
^{99m}Technetium-erythrocytes	Localization of gastrointestinal bleeding
^{99m}Technetium-sestamibi	Myocardial perfusion imaging agent evaluation of abnormal mammogram
^{99m}Technetium sodium pertechnetate	Cerebral radionuclide angiography, localization of placenta, imaging thyroid, salivary gland, and nasolacrimal drainage system, detection of vesicoureteral reflux
^{99m}Technetium-succimer	Evaluation of renal parenchymal abnormalities
^{99m}Technetium sulfur colloid	Imaging of reticuloendothelial cells in liver, bone marrow, and spleen; evaluation of gastrointestinal reflux/esophageal transit; and localization of lymph nodes draining tumor sites
^{99m}Technetium-tetrofosmin	Evaluation of myocardial perfusion
^{99m}Technetium-tilmanocept	Evaluation of lymph drainage from tumor sites
^{201}Thallium chloride	Evaluation of myocardial perfusion and localization of parathyroid hyperactivity
^{133}Xenon gas	Evaluation of pulmonary function and cerebral blood flow
^{90}Yttrium chloride	Radiolabeling of ^{90}Yttrium for radioimmunotherapy procedures
^{90}Yttrium-ibritumomab tiuxetan	Treatment of non-Hodgkin's lymphoma

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and coronary blood flow) with ^{123}I and ^{99m}Tc.[14] SPECT scans are sensitive for the detection of avascular necrosis of the femoral head, dementias, epilepsy, acute stroke, brain death, traumatic brain injury, Parkinson's disease, and acute cerebral infarcts.[15,16] Data on the use of SPECT scanning are too limited to use this imaging technique for the diagnosis of toxic injuries to the central nervous system and other organs.

Technetium-99 m (^{99m}Tc) is the most common radiopharmaceutical used for medical imaging.[9] Generators produce ^{99m}Tc by the decay of ^{99}Mo in an aluminum oxide column containing ^{99}Mo as sodium molybdate. Elution of this column with isotonic saline provides a source of ^{99m}Tc by yielding a stable solution of sodium pertechnetate ($Na^{99m}TcO_4^-$). Another important radiopharmaceutical is ^{123}I; this radionuclide easily combines with antibodies, peptides, and proteins for use in diagnostic nuclear medicine procedures.

Table 41.5 lists the FDA-approved radiopharmaceuticals used in radiotherapy and nuclear medicine imaging modalities. Diagnostic radiopharmaceuticals usually have short physical half-lives (hours to days) and emit low-energy γ-photons. In contrast, radioisotopes used in radiotherapy to ablate tissues and tumors deliver substantial radiation doses (i.e., β-particles from ^{131}I or ^{32}P) to selected tissue targets. Typical radiation doses from radionucleotides used in diagnostic imaging range from 3–14 mSv.[17] Radiation doses to other people near the patient are usually acceptably low. In a study of 80 adult patients receiving various diagnostic radiopharmaceuticals (^{111}In, ^{123}I, ^{99m}Tc, ^{201}Tl) in a nuclear medicine department, the maximum radiation dose rates at discharge ranged from 150 μSv/hour at 0.1 m from the patient, 30 μSv/hour at 0.5 m, and 7.3 μSv/hour at 1 m.[18] Only the bystander radiation dose from an ^{111}In leukocyte scan in an infant would have exceeded the 1-mSv level to the infant's parent, depending on the patient surface dose rate, parental habits, and the need for comforting the infant. ICRP Publication 128 provides a compendium of radiation information on major radiopharmaceuticals including effective radiation doses, absorbed organ/tissue radiation doses, biokinetic models, and biokinetic data.[19] The estimated effective doses from radiopharmaceutical administration depend on several factors, including the choice of biokinetic models, computational voxel phantoms used to simulate living tissues, and tissue radiosensitivity weighting factors.[20]

Radiotherapy

Radiopharmaceuticals used in radiotherapy typically emit most of their energy via β-particles rather than γ-photons, whereas most diagnostic radionuclides possess relatively short half-lives and emit low-energy (i.e., <300 keV) γ-rays only. The production of γ-rays increases radiation exposure of normal tissue beyond the targeted organ in the patient and health personnel involved with radiopharmaceutical administration.

Nuclear reactors produce most therapeutic radiopharmaceuticals by direct neutron activation of stable targets; however, charged-particle accelerators generate some of these isotopes. The half-lives of most therapeutic radionuclides are <10 days allowing multiple dosing. The half-life of the radiopharmaceutical must be compatible with the localization rate in the target tissue and clearance of the carrier molecule from normal tissue.[5]

TOXICOKINETICS

Absorption

Inhalation

The fate of inhaled particles (range 0.01–100 μm) depends primarily on particle size and their solubility in respiratory fluids. Particles of >100 μm usually settle on mucosal surfaces quickly before exhalation occurs, whereas particles of <0.01 μm are easily exhaled like gas molecules.[21] The upper respiratory tract is an excellent filter for particles of >7 μm in diameter; 90% of these particles are expectorated or swallowed. Inhaled particles of >3 μm impact large and medium-sized airways, whereas most particles of <0.5 μm deposit in alveoli and terminal bronchioles via random diffusion.[22] Mucociliary clearance removes most particles deposited on the bronchial mucosa and alveolar ducts within several hours; however, a significant portion of these smaller particles settles in the alveoli and alveolar ducts, where macrophages remove them or they enter the interstitial space directly. Thus, a soluble radionuclide may enter the systemic circulation directly by uptake through the alveolar membrane, or via particle transfer, to the lymphatic system. Macrophages can transfer insoluble radionuclides to peribronchial, hilar, and subpleural sites. For modeling purposes, the ICRP classifies the relative biological clearance of radionuclides into the following three categories based on the residence time for 1 μm particles: 1) D (days), half-time <10 days; 2) W (weeks), half-time 10–100 days; and 3) Y (years), half-time >100 days. The distribution of particles in the lung is not uniform, particularly for α-particles; however, this nonuniform deposition probably does not increase cancer risk compared with the uniform distribution of the same radiation amount throughout the lungs.[23,24]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Ingestion

The physical and chemical properties of a radionuclide determine the amount of chemical passing through biological membranes. Although several factors (e.g., pH, solubility of the attached matrix) affect the transfer, radionuclides are classified as *transferable* or *nontransferable*. Transferable radionuclides are soluble in biological fluid; therefore, the gastrointestinal tract easily absorbs these radionuclides. Nontransferable radionuclides are either insoluble at all pH (e.g., certain metals or oxides produced at high temperatures) or soluble only at acidic pH (e.g., divalent mineral cations); salts of the latter (e.g., rare earth metals, plutonium, trans-plutonic elements) polymerize into hydroxides as the pH rises. The solubility of a radionuclide and its complex depends on the pH and the location in the gastrointestinal tract with the pH varying from the acid pH of the stomach to the alkaline environment in the duodenum. No material is entirely insoluble; therefore, even a highly insoluble compound (e.g., high-fired thorium oxide) may contain a small soluble fraction.[25]

Poorly absorbed (i.e., <10%) radionuclides include americium, antimony, californium, cerium, chromium, cobalt, curium, iron, manganese, mercury, plutonium, ruthenium, silver, uranium, and zirconium. For these radionuclides, the lower colon receives the highest dose of radiation because this portion of the gastrointestinal tract has the slowest motility.[26] Cesium, iodine, and tritium are almost completely absorbed from the gastrointestinal tract. Intermediate absorption occurs for radium (20%), strontium (30%), and phosphorus (80%).

Wound

Intact skin is usually an adequate barrier to the entrance of radionuclides into the body, except for tritium.[27,28] Internal contamination from wounds occurs when the radionuclide enters the blood or spreads to the regional lymph nodes. The transferability of the radionuclide depends on the physical and chemical characteristics of the wound including the pH, solubility, tissue reactivity, and contaminant particle size.[29] Prolonged exposure to relatively insoluble compounds (e.g., plutonium oxide) may result in some translocation because of the alteration of their physiochemical properties after protracted contact with the immune system.

Elimination

The process of radionuclide elimination from the body occurs through both radiological decay and biological elimination. Radioactive decays release energy from the nucleus in the form of one or more types of ionizing radiation (i.e., γ-rays, α- or β-particles, positrons, neutrons) when they reach a more stable energy state; this process varies with individual radionuclides (e.g., $^{131}I = 8$ days; $^{137}Cs \cong 30$ years). The physical half-life (λp) represents the time to reduce the radioactivity (measured in becquerels) to half of the initial level from only physical decay, whereas the biological half-life (λb) represents the time to excrete half of the absorbed radionuclide dose from the body. The effective half-life (λe) reflects both processes, as noted in Equation 41.3. The value of the effective half-life is always shorter than either the biological or the physical half-lives.

$$1/\lambda e = 1/\lambda p + 1/\lambda b \qquad \text{(Equation 41.3)}$$

where

λp = physical half-life,
λb = biological half-life,
λe = effective half-life.

Maternal-Fetal Kinetics

The radiation dose absorbed by fetal tissue depends on placental permeability to the radionuclide, fetal affinity for the radionuclide, and the type of radiation emitted from the radionuclide.[30] Inorganic iodides readily cross the placenta, whereas protein-bound iodides do not. A maternal ^{131}I dose as low as 12.2 mCi (9.2 mCi during gestational weeks 10–15) may destroy the fetal thyroid.[31] Radioactive fallout from nuclear reactor meltdowns and nuclear bomb detonations may cause elevated radioiodine concentrations in fetal thyroids.[32] Fetal uptake of radioiodine is low prior to 12 weeks of gestation; subsequently, the fetal thyroid readily absorbs radioiodine. At gestational ages of 14–22 weeks, radioiodine uptake (55–75%) exceeds adult uptake with radioiodine concentrations in the fetal thyroid 3–10-fold higher than adult thyroids.[33] Consequently, fetal hypothyroidism and cretinism may occur in pregnant women exposed to ^{131}I therapy.[34] Most inert gases probably diffuse across the placenta easily; however, ^{81m}Kr pulmonary function tests are an exception because of the very short 13-second half-life. The passage of ^{99m}Tc across the placenta depends on the associated anion; the pertechnetate oxoanion easily crosses the placenta, whereas other ^{99m}Tc radiopharmaceuticals may not cross, depending on the individual kinetics and labeled cell type. ^{90}Strontium easily crosses the placenta with the highest fetal radiation doses occurring in the red marrow.[35,36] The mouse placenta

Sulfur	1	2	2	2
Zinc	2	1	2	1
Zirconium	0.2	1	0.2	1

Abbreviation: HTO = tritiated water (^3H_2O).

is less permeable to cesium than strontium.[37,38] Some animal studies suggest a wide range of maternal/fetal ^{137}Cs ratios following radiopharmaceutical exposure; however, human reports suggest the ratio is close to 1.[39] The International Commission on Radiological Protection (ICRP) provides a detailed guide to maternal-fetal radiation doses following exposure to a variety of radiopharmaceuticals.[40] Table 41.6 lists the adopted fetal/maternal and placenta/maternal ratios for element concentrations used in the ICRP biokinetic models used to calculate radiation dose coefficients for the embryo and fetus following maternal intake of radionuclides. These values relate to reference levels for summing external and internal radiation exposures to compare with radiation protection guidelines rather than assessments of individual radiation exposure in epidemiology studies.[41]

DOSE

The absorbed radiation dose in the target organ largely determines the amount of tissue damage along with dose rate, radiation quality factors, fractionation, and tissue sensitivity. Therefore, determinants of radiation dose (e.g., amount, duration) transferred from the environment to the tissue include the portal of entry, the target organ where deposition occurs, the type of particles and/or photons emitted from the radionuclide, physiochemical properties affecting radionuclide absorption and distribution in the tissues, and the effective radionuclide half-life.[29] Shorter half-lives correlate to higher energy emission rates. The amount of radiation absorbed by an organ depends in part on the affinity of a radionuclide for that organ. Iodine and alkaline earth metals (strontium, barium, calcium) accumulate in the thyroid and bones, respectively, whereas alkali metals (sodium, cesium, potassium) spread throughout the body.

Cosmic and Terrestrial Radionuclides

The radiation dose from ingesting primordial radionuclides is much larger than that from cosmic radionuclides.[3] The average annual effective dose equivalent in the United Kingdom from ingesting ^{14}C is ~12 μSv compared with 3 μSv for ^{7}Be.[43] External radiation from terrestrial radionuclide-emitting α- and β-particles is small compared with the radiation from inhaling radon daughters or ingesting terrestrial radionuclides. US ground surveys of radiation dose rates from exposure to external terrestrial radionuclides in outdoor US environments indicate the annual dose ranges of 0.35–1.8 mGy.[3] The actual radiation dose received by an individual indoors depends on the location and the construction materials. Masonry buildings attenuate most γ-rays from the ground;[43] however, indoor γ-ray dose rates are usually higher because of the contribution of inhaled radon daughters.

Table 41.7 lists the estimated annual dose equivalents to soft tissues and bones from naturally occurring

radionuclides. α-Particles from ^{210}Po and other members of the primordial series account for most radiation received by bones, whereas ^{40}K generates most radiation received by soft tissues.[44]

Medical/Industrial Radionuclides

Skin

Radiopharmaceutical-induced dermal injury depends on the half-life and energy emitted by the radioactive isotope. α-Emitting radionuclides do not usually cause dermal injury unless the skin barrier is not intact, whereas γ-emitting radionuclides (e.g., ^{137}Cs, ^{60}Co, ^{192}Ir) may cause dermal injury from the emission of β-particles and soft X-rays.[45] High-energy, short-lived radionuclide-emitting β-particles pose a risk, particularly to the hands of nuclear medicine technologists handling these isotopes without proper shielding. These particles also dramatically affected the skin of Pacific atoll residents following the Castle Bravo thermonuclear test and first responders at Chernobyl.[29] The most severely affected patients in the latter incident received dermal radiation doses exceeding 40 Gy; the subsequent desquamation and disruption of the basal layer provided a portal of entry for fatal infections in many immunosuppressed patients.[46] Long-term dermal complications of cutaneous radiation exposure at Chernobyl include epidermal atrophy, telangiectases, altered pigmentation, fibrosis, keratosis, ulcers, and basal cell carcinomas. Fallout from nuclear detonations may provide sufficient β-radiation to cause skin burns; however, the maximum external effective distance of airborne β-particles is ~2 m, with β-radiation diminishing quickly as the distance increases by more than a few meters. Syringes and vial walls may not provide sufficient shielding for high-energy isotopes (e.g., ^{90}Y, ^{188}Re, ^{166}Ho). Computer models of β-radiation exposure (e.g., elutions from ^{99}Mo/^{99m}Tc generators) suggest the basal layer of the skin receives ~1 cGy/hour per 3.7×10^{-4} Bq/cm^2 (1 rad/hour per μCi/cm^2) from ^{99m}Tc, ^{111}In, and ^{201}Tl.[47]

Fetus

The two stages of the developing conceptus comprise the initial stage of organ formation (embryo, conception to day 56 postconception) and the subsequent growth stage (fetus, day 57 postconception to birth). Embryo and fetal radiation doses from maternal exposure to radionuclides depend on several factors including radiation type and amount, maternal and fetal radiopharmaceutical kinetics (absorption, distribution, elimination, diffusion across placenta), fetal age/growth, and amount of penetrating radiation (energetic β-particles, γ-rays, X-rays). Radiation doses to the offspring typically are similar or lower than the reference adult with a few exceptions (^{45}Ca, ^{14}C, ^{59}Fe, ^{3}H, $^{125/131}$I, $^{224/226}$Ra, $^{89/90}$Sr, ^{35}S).[42] The two major categories of fetal irradiation from maternal radionuclide exposure involve isotopes that diffuse across the placenta (e.g., strontium, iodine, gallium, xenon) and other radiopharmaceuticals (e.g., cesium, cerium, most lanthanides) limited by the placenta. The fetal/maternal concentration ratio of an element reflects the estimated ability of the element to pass the placenta; a ratio of >1 indicates the placenta easily passes the element, whereas ratios of <1 indicate the placenta acts as a barrier to the element. Table 41.6 lists placenta/maternal and fetal/maternal ratios for some common radionuclides.

The ICRP uses fetal/maternal concentration ratios to calculate the effective dose in offspring following maternal radionuclide intake before and after pregnancy for radiological protection purposes, rather than for evaluation of individual radiation exposures. The calculated value is expressed as the ratio of the effective dose of the offspring to the effective dose of the reference adult ($E_{\text{offspring}}/E_{\text{adult}}$). This value for a specific radionuclide depends on exposure time in relation to conception, fetal growth, and the physiochemical properties (e.g., gastrointestinal/pulmonary absorption, effective half-life). Tritiated water, ^{14}C, and ^{35}S easily enter the maternal circulation, distribute into body tissues, and diffuse across the placenta following ingestion. The offspring doses of these three radionuclides typically are up to twofold higher than adult doses for maternal ingestion during pregnancy, with the doses after ^{14}C dependent on the chemical form. Significant uptake of alkaline earth elements (Ba,

Ca, Ra, Sr) by the fetal skeleton occurs, particularly following exposure during the large fetal growth at the end of pregnancy. Although Ba, Ca, Ra, and Sr are chemically similar, the placenta limits the uptake of these radionuclides other than calcium; consequently, the effective doses of Ba, Ra, and Sr are lower than calcium. Additionally, the $E_{\text{offspring}}/E_{\text{adult}}$ ratio for ^{89}Sr is higher than ^{90}Sr because the half-life of the latter is much longer (29 years) than the former (50 days). Radioiodine uptake is much lower in the fetus than the mother until gestational week 12 when fetal thyroid function begins. Subsequently, the effective fetal dose substantially exceeds the mother's dose, particularly for the short-lived ^{131}I isotope (half-life, 9 days) compared with ^{125}I (half-life, 60 days). The poor gastrointestinal absorption and placental uptake of ^{241}Am and ^{239}Pu limit the fetal radiation dose of these predominately α-emitters to levels significantly below the adult reference value.

Tables 41.8 and 41.9 list the ratios of the effective dose to the adult reference dose following four oral and pulmonary exposure scenarios, respectively, before and during pregnancy. A value of >1 indicates the offspring dose is greater than the maternal dose, whereas a value of <1 indicates the maternal dose is greater than the offspring dose.

CLINICAL RESPONSE

Table 41.10 lists the sites of harmful tissue reactions (deterministic effects) soon after the inhalation and internal deposition of sufficient doses of a radionuclide along with cancer sites at risk following extended internal deposition of these radionuclides (stochastic effects).[48] Deterministic effects are very uncommon because of the large radiation doses required to cause these effects. Recognized serious deterministic effects associated with radionuclide exposures include the poisoning of Alexander Litvinenko (^{210}Po); bone marrow suppression, radiation burns, and deaths from the Goiania, Brazil, incident (^{137}Ce); and radiation pneumonitis and pulmonary fibrosis in early Mayak plutonium workers in the Soviet Union (primarily ^{239}Pu).

TABLE 41.10. Following inhalation and internal deposition of radionuclides in sufficient radiation doses, organs/tissues affected by harmful tissue reactions (deterministic effects) soon after exposure or cancer (stochastic effects) from extended exposure. The absorption type represents the estimated absorption rate of the radionuclide from the respiratory tract into the blood using ICRP models.[49] (Adapted from National Council on Radiation Protection and Measurements (NCRP)).[48]

Radionuclide (Emission)	Absorption Type[a]	Tissue with Deterministic Effects	Tumor Sites with Stochastic Effects
$^{231}AmO_2$ (α)	Moderate (M)	—	Bone, lung
$^{144}CeO_2$ (γ and/or β)	Slow (S)	Lung	Lung
$^{137}CsCl$ (β and/or γ)	Fast (F)	Bone marrow	Total body
^{60}Co oxides (γ)	Slow (S)		Lung
$^{3}H_2O$ (β)	Fast (F)	—	Total body
^{131}I vapor (β)	Fast (F)	Thyroid	Thyroid
^{210}Po (α)	Moderate (M) or fast (F)	Lung, kidney, liver, bone marrow, others	Lung, kidney, blood cells, spleen
$^{238}PuO_2$ (α)	Slow (S) or moderate (M)	Lung, thoracic lymph nodes, bone liver	Lung, bone, liver
$^{239}PuO_2$ (α)	Slow (S) or moderate (M)	Lung, thoracic lymph nodes	Bone
^{226}Ra sulfate (α)	Moderate (M)		Bone
^{222}Rn and decay products	Fast (F)		Lung
$^{106}RuO_2$ (β)	Slow (S)		Lung
$^{90}SrCl_2$ (β)	Moderate (M) or fast (F)	Bone marrow	Bone marrow, bone
^{232}Th (α)	Slow (S)		Lung

[a] Absorption rate from the respiratory tract into blood based on Internal Commission on Radiation Protection (ICRP) models in ICRP Publication 66.

Tissues at risk for the development of cancer following prolonged exposure to internal deposits of radionuclides are listed in Table 41.10. Recognized stochastic effects include thyroid cancer after the Chernobyl nuclear reactor accident and ^{131}I radiotherapy, bone cancer in radium dial painters and ^{224}Ra-treated ankylosing spondylitis patients, bone and liver cancers in Thorotrast®-treated patients (^{232}Th and progeny), and lung cancer in underground uranium miners (^{222}Rn and progeny). Similar tissues are at risk following ingestion or absorption through wounds, except for insoluble forms retained in the lungs. Although wounds in contaminated areas of skin indicate possible radionuclide intakes, very heavy contamination is necessary to produce significant internal deposition including soluble radionuclides.

DOSIMETRY

Because the effectiveness of treatment depends on the type of radionuclide involved in the incident, optimal treatment necessitates a good history including initial determination of the location and time of the accident, presence of external contamination, identification of the radionuclides involved, route of exposure, and amount of radionuclide released. Helpful information includes size of released particles, solubility of the radionuclide, corrosiveness or toxicity of the radionuclide complex, and the effective half-life.

Conversion Factors

$1\,pCi = 0.037\,Bq$
$1\,pCi/L = 37\,Bq/m^3 = 2.22\,decays/minute/L$
$1\,Bq = 27\,pCi$
$1\,Bq/m^3 = 0.027\,pCi/L = 60\,decays/minute/m^3$

Analytical Methods

Although basic dosimetry calculations produce relevant clinical information sufficient to make treatment decisions, health physicists typically use complex mathematical functions to refine estimates of radiation exposures. Except for direct deposition of radionuclides into the body, the incorporation of the radionuclides is a time-dependent process that depends on the physiochemical characteristics of the individual radionuclide.[50] Estimation of absorbed radiation dose requires measurements of external radiation levels and the duration of exposure. Deriving estimates of internal radiation doses from whole-body counting methods introduces the possibility of errors resulting from nonhomogenous radionuclide distribution and inaccurate assumptions regarding radioisotope ratios (e.g.,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

americium/plutonium) following ingestion. Prompt identification of the type and amount of contamination is necessary to optimize treatment. Monitoring should begin within 24–48 hours after the radiation release to identify people with radiation doses exceeding the thresholds for serious deterministic effects.[26] Ideally, treatment for serious internal contamination should begin within 1–4 hours. Most episodes of internal contamination result from the inhalation of radioactive material, whereas a few cases of incorporation develop after the gastrointestinal absorption of the radionuclide or absorption from open wounds. Estimation of dose based on the results of bioassays is subject to several uncertainties including: 1) biological variability, 2) accuracy of the model, 3) interference from other radionuclides, 4) precision of analytical techniques, and 5) sample collection procedures.

A wide range of scenarios exist for individuals internally contaminated with radionuclides; and the type of instruments appropriate for screening persons exposed during these scenarios varies accordingly.[51] Accidental exposures in the medical, research, or industrial settings typically involve only a few individuals. Dose assessments usually occur at local facilities with bioassays and potentially whole-body counting using available instruments. Dispersal of a radionuclide with a radiological dispersion device (i.e., terrorist event) would involve tens of victims; nuclear medicine γ-cameras are makeshift whole-body counters for dose assessment and medical triage during these incidents. More rapid screening instruments are necessary following the radiological dispersal devices affecting hundreds or more patients. The use of portable survey meters near the safe zone is a first approximation used to triage individuals into ranges of effective dose (e.g., <50 mSv, 50–250 mSv, 250–500 mSv, >500 mSv) to enhance the triage process and medical treatment.

Instrumentation

Prompt initiation of appropriate triage and decontamination procedures as well as medical management requires knowledge of the presence of the radiation type, including α-particles, β-particles, or γ-radiation. Survey instruments usually measure γ-rays, α-particles, and/or β-particles rather than specific radionuclides. The best measure of internal contamination from γ-ray-releasing radionuclides is the use of detectors close to the body (i.e., whole-body or partial-body monitoring).[52] During triage situations, some handheld instruments and unshielded high-resolution detectors have sufficient sensitivity to identify accident victims requiring medical treatment. Portable instruments allow the detection of external contamination on the skin and clothing, quantification of the committed effective dose for victims of lower levels of internal contamination, identification of patients needing chelation therapy, and data collection for the estimation of individual health risks. General survey instruments with spectroscopy (e.g., handheld NaI crystal detectors with isotope identification via γ-spectroscopy picture) range in size from handheld to palm/pager size. Isotope libraries typically include Naturally Occurring Radioactive Material (NORM), nuclear industry, research, and industrial isotopes. Depending on the dose rate and energies, these detectors can often resolve isotopic mixtures. Handheld instruments are routinely used to measure ^{131}I and ^{125}I in the thyroid; they also are potentially useful for evaluating radiation exposures from ^{137}Cs, ^{60}Co, and ^{75}Se.[52] The main disadvantages of handheld detectors are their inability to quantify individual components in a radionuclide mixture released during a reactor accident and their lack of spectrometric capability.[52] The latter requires identification of radionuclide-specific action levels prior to measurements.

These relatively simple instruments accurately detect primarily radionuclide-emitting γ-rays with energies >200 keV and high emission probability. Handheld instruments (e.g., Mini Instruments type 44A) are available for the routine measurement of ^{131}I, ^{125}I, and ^{137}Cs using NaI(Tl) crystal detectors; the US Centers for Disease Control and Prevention (CDC) published tables to convert net count rates to effective radiation doses of 50, 250, and 500 mSv.[53] Calibration factors for these tables include gender, probe position, distance from probe to person, identity of radionuclide, particle size, lung solubility class, and primary route of absorption. Although radionuclides are detected by handheld devices (e.g., ^{60}Co, ^{75}Se, ^{192}Ir), determination of individual doses for highly exposed persons requires more sophisticated instruments.[52] Systems using unshielded, high-resolution detectors are not affected by the presence of naturally occurring radionuclides because NORM radionuclides do not interfere with the γ-ray spectrum.

Geiger counters measure γ-ray exposure rates and the presence of β-radiation depending on the type of probe used; both Geiger and scintillation detectors can typically detect internal contamination by γ-ray and high-energy β-particle-emitting radionuclides. The detection of α-particle or low-energy β-particle-emitting radionuclides (e.g., plutonium) requires special detectors or α-spectroscopy. Direct whole-body counters or chest counters are sensitive measures of the magnitude of internal radiation (e.g., ^{137}Cs, ^{134}Cs); however, the whole-body counters cannot detect the low levels of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Shielded, mobile instrument	NaI(Tl) (7.6 × 13 × 41)	10.0	100	0.0010
Shielded, mobile instrument	NaI(Tl) (12.5 × 12.5)	10.0	450	0.0060
Shielded, mobile instrument	NaI(Tl) (5 × 5)	10.0	5,000	0.0700
Shielded, laboratory	4 HPGe (8 × 6.8)	20.0	33	0.0005
Shielded, laboratory	HPGe (10.6 × 7.5)	45.0	30	0.0004
Shielded, laboratory	5 NaI(Tl) (10 × 15)	45.0	18	0.0003

[a] Although reading is instantaneous, the count should be read for ~20 seconds to obtain the average value. [b] The scenario assumes whole-body activity at the detection limit 1 day after an adult inhales ^{137}Cs with absorption type F and activity median aerodynamic diameter of 5 μm.

external radiation emitted by internal contamination with many radionuclides. Consequently, results within the first few days can be confusing, even after the completion of decontamination measures. New field deployable γ-ray spectrometers with NaI(Tl) crystal detectors allow the rapid measurement of whole-body contamination by ^{131}I and ^{137}Cs with detection limits of ~1 kBq; this detection limit corresponds to a radiation dose of 1 mSv 1 day after exposure.[54] These monitors allow real-time spectrum analysis including thyroid (i.e., ^{131}I activity) and simple whole-body (i.e., estimate of internal contamination) measurements in the field. Portable portal monitors are available to measure β-/low γ-radiation (e.g., Ludlum 52-1-1, Ludlum Measurements, Inc. Sweetwater, TX);[55] several government agencies responsible for emergency preparedness (e.g., Canadian National Calibration Reference Centre for *In Vivo* Monitoring) evaluate instrumentation for field use.[56]

Portable hyper-pure germanium-based radionuclide identifiers (e.g., Detective™, Advanced Measurement Technology, Oak Ridge, TN) are available as easily deployable whole-body monitors that operate as standalone γ-ray spectrometry systems with the addition of appropriate software. These unshielded monitors cannot be operated in environments with significant contamination. The use of high-resolution high-purity germanium (HPGe) detectors allows the identification of individual radionuclides in mixtures; however, these very expensive systems are shielded and more difficult to transport.[57,58] Laboratory-based whole-body monitors with NaI(Tl) or HPGe detectors can identify radionuclide intakes of ≪1 mSv for radionuclide-emitting γ-rays containing energies of >100 keV.[59,60] Screening of persons exposed to radionuclides emitting few or low-energy γ-rays (e.g., ^{241}Am) requires shielded instruments with large detectors. Table 41.11 compares the detection limits, scanning time, and lower limit of detection for a specified ^{137}Cs exposure using several types of instruments for the detection of external radiation from internal contamination. The more sensitive instruments can identify radionuclide intakes occurring up to 100 days after exposure by detecting whole-body doses below 1 μSv. The relatively short half-life of ^{131}I limits screening for contamination by this radionuclide to a period of several weeks. External radiation emission from radiation sources inside the body does not occur when the ingested or inhaled radionuclide emits radiation incapable of penetrating the skin (e.g., α-particles). Urine samples are necessary to screen patients for this type of internal contamination and some radionuclides emitting few or low-energy γ-rays (^{241}Am), depending on the availability of sophisticated instrumentation. α-Spectrometry is the most common technique for determining the presence of α-emitters (e.g., actinides) in biological samples; however, inductively coupled plasma/mass spectrometry (ICP/MS) is very sensitive for measurements of long-lived radionuclides.[61] Analysis of urine samples by ICP/MS allows the detection of internal contamination by uranium, thorium, and actinides in the 1–2 μBq/L range, whereas most routine ^{239}Pu and ^{240}Pu bioassay analyses involve detection by α-spectrometry.[62] The establishment of a Radiation Monitoring Unit may be necessary to determine the extent of internal and external contamination.

Sample Collection

Sample analysis at the scene (e.g., nasal smears) may indicate the presence of inhaled radioisotopes/radio-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 41.12. Sampling collection methods for internal contamination from radionuclides. (Ricks).[63]

Sample	Purpose	Method
Urine	Internal contamination	Four consecutive 24-hour urine specimens in urine collection container
Feces	Internal contamination	Four daily fecal specimens in refrigerated or frozen plastic containers
Vomitus	Internal contamination	Refrigerated or frozen plastic containers
Sputum	Respiratory contamination	5% propylene-glycol aerosol for deep specimen
Irrigating fluids	Radiological assessment	Save in sealed and labeled glass or plastic containers

active material assuming an absence of cross-contamination from other sources (e.g., hands). The extent and success of removing external contamination in the field is an important determinate of the significance of residual contamination in the Emergency Department. Analysis of samples or clothing collected at the scene may be necessary to establish the identity of the radionuclide responsible for the accident. The extent of external radiation, the early initiation of therapeutic measures, and the presence of associated injuries will influence the prognosis of the patient. In the presence of suspected internal contamination, samples should be collected to assess the extent of internal contamination. Table 41.12 lists the type and method of collecting these samples.

The analysis of wet nasal swabs gathered and dried in the field after a few minutes of exposure provides the most reliable method of determining the presence or absence of inhaled radioactive particles.[26] Nose blowing, insufflating water, and delayed collection (i.e., >20 minutes) reduce the accuracy of this method. Geiger counter counts of >500 dpm from both nostrils suggest significant exposure to radiation, whereas counts of <50 dpm indicate limited exposure. Elevated counts in only one nostril suggest external contamination. The amount of internal contamination with soluble radionuclides (cesium, iodine, tritium) can be estimated by the analysis of the urine for radioactivity and the use of elimination models developed by the NCRP.[64]

HEALTH SURVEILLANCE

Environmental Exposure

The Agency for Toxic Substances and Disease Registry (ATSDR) established a minimum risk level (MRL) of 4.0 mSv (400 mrem) for acute-duration (14 days or less) external exposure to ionizing radiation.[65] The derivation of this MRL was based on the development of neurological effects in children 10–11 years of age exposed at gestation weeks 8–15 during the atomic bombings of Hiroshima and Nagasaki.[66] The observed outcome in this study was an estimated reduction of 25 IQ points/Sv, resulting in a potential decrease of 0.25 IQ points at the MRL assuming an uncertainty factor of 3. The recommended MRL for chronic-duration (365 days or more) external exposure to ionizing radiation is 1.0 mSv/year (100 mrem/year) above background.

Pregnancy

Women should receive the minimum amount of medical radiation consistent with obtaining necessary clinical information, regardless of pregnancy status. During pregnancy, consideration should be given to the consequences of delaying the procedure, the fetal dose delivered, and the likelihood of additional medical procedures. Ultrasound has replaced some medical imaging techniques using radiopharmaceuticals. Significant risks of radiation-induced abnormalities occur at fetal doses of >100 mSv (10 rads). Radioiodine should be avoided during pregnancy unless it is necessary for the medical treatment of the mother and no other adequate substitute is available.

Occupational Exposure

Maximum levels for radionuclide deposition are based on dosimetry calculations using the same dose limits as those critical organs would receive for external radiation. The one exception is the radionuclides that deposit in bones because sufficient epidemiological data are available from radium exposure to allow direct calculation of allowable levels.

National Regulatory Commission

The US National Regulatory Commission (USNCR) established maximum annual radiation doses (Annual Limit on Intake, ALI). The ALI is the smaller value of the annual intake of a given radionuclide that would result in a committed effective dose equivalent to 50 mSv (5 rems, stochastic ALI) or a committed dose equivalent to 500 mSv (50 rems, nonstochastic or deterministic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ALI) to any individual organ or tissue. The current radionuclide table for the former is available online at https://www.nrc.gov/reading-rm/doc-collections/cfr/part020/appb/. The "E" notation refers to the power of 10; a value of 6E–02 represents a value of 6×10^{-2} (i.e., 0.06), 6E+2 represents 6×10^{2} (i.e., 600), and 6E+0 represents 6×10^{0} (i.e., 6). The derivation includes multiplying the committed dose equivalent to an organ or tissue by a weighting factor, W_T.

For aerosols, the inhalation ALI and DAC assume an activity median aerodynamic diameter (AMAD) of 1 μm; the value depends on the retention classification (D, W, Y) of radioactive material in the pulmonary region of the lung. The nonstochastic ALIs were derived to avoid deterministic effects (e.g., acute tissue damage, organ dysfunction). The radiation limits for the public are 10% of the occupational limits.

Calculations of the concentrations of a radionuclide in air (Derived Air Concentration, DAC) and water involve limiting the values below the ALI in air and water, respectively. The derived air concentration values are designed to control chronic occupational exposures. These derived levels are specified for a given radionuclide depending on the physiochemical properties of the radionuclide. For radionuclides with long half-lives, the calculations are conservative because the limits assume that the body already contains the maximum permissible activity, whereas the controls begin before exposure. The ALI dose limits are designed for radiological protection; therefore, these values should not be used to calculate cancer risks.

International Commission on Radiological Protection

International Commission on Radiological Protection (ICRP) and USNRC have similar guidelines.

TREATMENT

Effective treatment requires identification of the specific isotope and an estimation of the internal radiation dose based on the calculated internal dose evaluated over 50 years (committed radiation dose) adjusted for the year of intake.[67] The presence of contamination in/around nostrils, mouth, open wounds, and/or face increases the likelihood of internal contamination. Identification of the radionuclide is critical because medical management is isotope-dependent. Of >8,000 isotopes, only ~10–15 are important isotopes in the civilian and military sectors including the Industrial 3 (^{60}Co, ^{137}Cs, ^{192}Ir), University 5 (^{14}C, ^{252}Cf, ^{125}I, ^{131}I, ^{32}P), and Military 5 (^{241}Am, ^{3}H, ^{239}Pu, ^{235}U, ^{238}U).[67] Table 41.13 lists the major categories involved with the medical management of internal contamination.

Several US government websites are available for valuable guidance on skin/wound decontamination, enhanced elimination, and chelation, including https://orise.orau.gov/reacts/ (Radiation Emergency Assistance Center/Training Center – REAC/TS, general information: 865-576-3131/after hours: 865-576-1005) and https://remm.hhs.gov/ (Radiation Emergency Medical Management, US Department of Health & Human Services). These websites provide algorithms for the diagnosis and management of internal contamination with links to the treatment of specific isotopes. Internal contamination usually occurs with external contamination except in unusual circumstances (e.g., inhalation and/or ingestion of fallout, intentional contamination of food or beverage). External contamination involves the deposition of radioactive material on the surface of the body. Treatment consists of removing the radioactive material (e.g., disrobing, cleaning the surface and any contaminated wounds); external contamination is typically easy to detect and remove. Internal

TABLE 41.13. Major categories of medical management of internal contamination along with examples of specific isotope, mechanism of action, and agent used.

Category	Isotope	Mechanism of Action	Agent
Alter absorption	Cesium, rubidium, thallium	Reduce gastrointestinal absorption	Prussian blue
Altered toxicokinetics	Uranyl ions	Inhibit binding of renal tubule surface proteins	Sodium bicarbonate
Block uptake	Radioiodine	Decrease thyroid uptake	Oral potassium iodide
Bronchoalveolar lavage	Plutonium (insoluble, inhaled contamination)	Direct removal	Lavage
Chelation	Plutonium	Binding/excretion	DTPA
Displacement	Strontium	Competitive binding of calcium	Oral aluminum hydroxide, IV calcium
Early excision	Fission-activation products	Minimize absorption	Surgery
Isotopic dilution	Tritium	Dilution/excretion	Increase fluid hydration

Abbreviation: DTPA = diethylenetriaminepentaacetate.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

contamination involves inhalation, ingestion, or dermal absorption of radionuclides that may concentrate in specific organs (e.g., thyroid, bone). Once inside the body, the kinetics of most radionuclides and their stable isotopes are similar.

Treatment is more complicated for internal than external contamination, often requiring drugs to reduce radionuclide absorption and/or enhance radionuclide elimination. Efficacy of these drugs depends on the selection of the appropriate drug for the radionuclide exposure and prompt administration (i.e., within several hours) of those drugs. Uptake of some radionuclides (e.g., ^{131}I) is rapid. One hour after the intravenous administration of ^{241}Am and ^{242}Cm to experimental animals, the blood contains 3–10% of the original dose with most of the radionuclide dose deposited in bone.[68] Frequently, few data are available on the effectiveness of these treatment modalities to reduce delayed health risks (e.g., cancer). Currently, available treatment techniques can reduce the body burden of incorporated radionuclides by factors ranging from 2–10;[26] however, treatment must begin within a few hours of exposure to optimize efficacy. The medical effects from internal contamination depend on the radiation dose, susceptibility, patient age (young children have greater susceptibility and longer expected exposure), and the general health of the patient. Consequently, the decision to initiate chelation should include a careful analysis of the estimated risks and benefits in consultation with radiation experts (Radiation Emergency Assistance Center/Training Center – REAC/TS, https://remm.hhs.gov, 24-hour phone: 865-576-3131/865-576-1005 after hours and/or Radiation Injury Treatment Network, https://ritn.net/, 612-884-8276; medical toxicologist; radiation health physicist/officer). Epidemiology studies suggest the cancer risk is not statistically evident below absorbed whole-body radiation doses of 0.1 Gy for the bone marrow and thyroid; for other organs, the estimated threshold radiation dose is 0.5 Gy.

First Aid

Associated injuries usually determine the need for first-aid measures; neither internal nor external radiation produces immediate life-threatening injuries. If radioactive contamination is suspected, gloves should be worn and the patient wrapped in a plastic sheet to prevent the spread of contamination. Serious overexposure to radiation is usually not a problem for health personnel unless a catastrophic event (e.g., Chernobyl) occurs; first aid should proceed as outlined under the treatment section on ionizing radiation incidents.

Triage

The main goal of radiological triage following an incident is the identification of patients most likely to benefit from further medical care. Governmental and institutional agencies (e.g., ICRP, NCRP) established action levels to guide patient triage following the release of radioactive radionuclides. The consensus of these agencies indicates that patients in radiation incidents receiving a committed effective dose exceeding 200 mSv should be considered for medical treatment.[52] The ICRP indicates clinically relevant functional impairment of tissues is unlikely at doses of <0.1 Gy with the threshold for deterministic effects being >1 Gy for most tissues. The IAEA uses a relative biological effectiveness (RBE)-weighted absorbed dose of 2 Gy-Eq for red bone marrow and 30 Gy-Eq for the lung, assuming the RBE for photons is 1, 7 for α-emitters in the lung, and 2 for α-emitters in the red bone marrow.[69] The IAEA recommends immediate medical evaluation, chelation if available, and accurate measurements of the organ-specific radiation doses exceeding their reference levels. The NCRP developed a Clinical Decision Guide for the maximum once-in-a-lifetime radiation exposure for stochastic risk that avoids deterministic effects. The RBE-weighted values for the red bone marrow and lungs were 0.25 Gy-Eq and 1 Gy-Eq, respectively. For most radionuclides and solubility types, Clinical Decision Guide values are lower for stochastic than deterministic (nonstochastic) risks. Nuclear detonation produces a complex environment where destruction of infrastructure, patient trauma, and limited resources create many triage issues. The Exposure and Symptom Triage (EAST) tool combines exposure maps with clinical assessments and single lymphocyte counts, if available, to identify patients with moderate radiation exposure (2–6 Gy) most likely to benefit from priority evacuation and cytokine treatment.

Decontamination

The Radiation Emergency Medical Management website (https://remm.hhs.gov/contamonly.htm#skip) provides specific guidance on decontamination measures for localized skin, open wounds, body cavity entrance sites (nose, mouth, ear), eyes, and hairy areas. The goal of skin and orifice decontamination is the reduction of the risks for acute dermal injury, internal contamination, and contamination of the environment and medical personnel.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Skin

The goal of localized skin decontamination is the reduction of external contamination to ≤2 times the background radiation level beginning with two decontamination cycles (tepid water, mild pH-neutral soap) and, if feasible, a radiation survey after each cycle.[70] The horny layer of the skin is the most important barrier to penetration of radionuclides into the subcutaneous tissue and the systemic circulation. The lower layer of the stratum corneum can absorb and then release α-emitters within 24–48 hours after satisfactory skin decontamination.[29] Most contamination resides in the upper horny layer; this tissue desquamates in a few days. The treatment section for ionizing radiation incidents lists procedures for skin decontamination. Most radioactivity can be removed without seriously irritating the skin; therefore, excessive skin trauma from decontamination measures is unnecessary and allows systemic absorption of the radionuclide. Contaminated hair should be removed with clippers if contaminated by long-lived α-emitting radionuclides. Shaving should be avoided because of the tendency for radioactive material to enter hair follicles, where removal is difficult after the shaving process. Chemical methods of eliminating surface radioactivity seldom are necessary except for new radioactive deposits from wound seepage and extrusion of retained, radioactive foreign bodies.

In a 64-year-old worker with facial burns and multiple ^{241}Am-containing, imbedded foreign bodies following the explosion of an ion exchange column containing nitric acid and ^{241}Am, the efficacy of various decontamination measures was similar during the first 2 weeks of decontamination. Subsequently, the most comfortable decontamination measures were administered.[71] Decontamination measures in this incident included Ca-DTPA-pHisoHex or shampoo, 2-hour sweat rinse, Schubert's solution-pHisoHex or shampoo, and Clorox-rinse or shampoo. The Ca-DTPA solution was diluted 1 part Ca-DTPA to 2 parts normal saline.

Wound

All open wounds are contaminated until proven otherwise. Radionuclide absorption from a wound depends on a complex interaction between physiochemical parameters (solubility, pH, particle size, mass injected, specific gravity), biological factors (type of tissue, tissue perfusion, deposition depth, particle dispersion in the fascial planes), and the inflammatory response to the radionuclide or its complex. Wound decontamination should precede skin decontamination with techniques (sterile waterproof drapes, medium pressure irrigation with sterile saline) similar to the removal of foreign bodies. Wound radioactivity should be measured before and after decontamination measures. Embedded, radioactive particles should be lifted from the wound with forceps. If contamination levels remain high after primary irrigation, surgical debridement of the wound is an option after obtaining expert medical and health physics advice. The use of skin biopsy punches is not a routine treatment, but these instruments can be useful to remove persistently contaminated tissue around a puncture wound with expert consultation (e.g., Radiation Emergency Assistance Center/Training Center – REAC/TS, general information 865-576-3131/865-576-1005 after hours; or equivalent expertise) if important underlying structures are not damaged. Irrigation fluid should be collected and analyzed for its effectiveness in reducing radioactivity from the wound including removal of α-particles when present. Contaminated drapes, instruments, and dressings should be discarded prior to the beginning of the next irrigation.

With expert consultation, excision of the wound margins may be necessary, particularly if the wound margins are jagged or contamination is spread in the facial planes. The extent of the excision depends on clinical judgment considering the consequences of the excision and the amount of residual radiation. Long-lived α-emitters (e.g., plutonium) are the most serious long-term threats. Insoluble materials often form granulomas that can be detected and removed in 6 months. Follow-up wound counts may be necessary to evaluate the extent of wound contamination following external decontamination. Topical application of element-specific chelators should be considered, when the area of residual skin contamination is extensive and the radionuclide is soluble. Upon completion of decontamination as determined by the lack of further removal of radioactive material, the wound should be dressed with a waterproof dressing. All cases of suspected internal wound contamination should undergo analysis of urine and feces for radioactivity and/or whole-body counts to estimate residual internal contamination.[63]

Orifices and Eyes

Uptake of radioactive material may occur more rapidly through mucous membranes and body orifices than intact skin. Therefore, contaminated orifices require prompt removal of radioactive particles with special attention to prevention of contamination spreading through the nasal-lacrimal duct, ruptured

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tympanic membranes, and/or the gastrointestinal tract. Decontamination proceeds in the following order: 1) open wounds, 2) body orifices, and 3) intact skin. Ruptured globes should not be irrigated. After X-rays to exclude penetrating shrapnel in the globe, the eyes can be gently irrigated with copious amounts of saline or water if the globe is intact and examination indicates the presence of corneal contamination. The eye should be irrigated with the lids retracted and the stream directed from the medial canthus to the lateral canthus to prevent radioactive particles from entering the nasolacrimal duct.

Assessment of oral contamination involves gargling with water, expectorating, and a survey for evidence of contamination. If decontamination for oral contamination is needed, treatment includes brushing the teeth with toothpaste, 3% citric acid rinse, and 3% H_2O_2 gargles (pharyngeal contamination). Each nostril should be swabbed and surveyed for contamination including mucous from blowing their nose. Contaminated nostrils should be irrigated with saline as the head is tilted forward and nose pointed at the floor with careful attention to avoid swallowing the irrigation solution or pushing fluid down the nasal passages.

Reduced Absorption

Emetics/Stomach Lavage/Cathartics

Few data are available to guide gut decontamination following internal contamination with radionuclides. The efficacy of ipecac is unproven, and data to compare the effectiveness of the syrup of ipecac with stomach lavage following internal contamination are unavailable. Stomach lavage quickly removes material from the stomach; however, this technique potentially disrupts the pharyngeal and esophageal mucosa. There are inadequate data to document the efficacy of cathartics. This procedure has a theoretical advantage of reducing transit time in the colon, where relatively insoluble radionuclides may reside for hours. Additionally, the amount of radionuclide removed is time- and technique-dependent with clinical presentation typically after the 1–2 hours following exposure.

The option is the administration of a chelating agent before pushing the radioactive material through the stomach and into the duodenum where absorption occurs. These are radionuclide-specific and should be administered with expert advice. Aggressive treatment with traditional gastric decontamination agents (emetics, stomach lavage, cathartics) probably is not efficacious.

Binders

Aluminum-containing antacids in a single oral dose of 100 mL reduce intestinal absorption of radioactive strontium. Alkalinization of the stomach may increase the formation of less soluble hydroxides of certain metals; the acid milieu of the stomach reduces chromium absorption by converting hexavalent to less soluble trivalent chromium. Barium sulfate reduces radium and strontium absorption by forming relatively insoluble sulfates.

Magnesium sulfate is a cathartic that forms relatively insoluble sulfates with certain radionuclides (e.g., radium). Phosphorus therapy involves hydration plus phosphate binders. NCRP-suggested phosphate binders for ^{32}P include aluminum carbonate, aluminum hydroxide, potassium phosphate, dibasic potassium phosphate, sevelamer, sodium glycerophosphate, and sodium phosphate.[72] Phosphates demonstrate similar properties by reducing the gastrointestinal absorption of strontium.

Blocking and Binding Agents

The US FDA approved two agents for reducing internal contamination of radionuclides by blocking (potassium iodide) or binding (Prussian blue) the radionuclides. *Blocking agents* reduce the radionuclide uptake by saturating tissue with nonradioactive elements, whereas *isotopic dilution* refers to the reduction of radionuclide absorption by the administration of a stable compound. Blocking agents inhibit the uptake of radionuclides when administered before incorporation of the radionuclide into the tissues. Little data exist on radionuclide clearance to guide management using blocking agents, dilution, hemodialysis, or hemoperfusion.

Potassium Iodide

Potassium iodide (KI) in a single daily dose of 390 mg for 7–14 days is an effective blocking agent that prevents ~50% of radioactive iodine (^{131}I) uptake into the thyroid gland when administered within 6 hours of exposure; the effectiveness of this blocking agent rapidly diminishes by 12 hours postexposure. The occurrence of adverse effects following iodine administration (rash goiter, hypothyroidism, thyrotoxicosis, parotitis, fever, arthralgias/myalgias) requires clinical judgment regarding the radiation dose necessary to justify iodine administration. Adjunctive blocking therapy includes the use of propylthiouracil (100 mg t.i.d. for 8 days) and methimazole (10 mg t.i.d. for 2 days followed by 5 mg t.i.d. for 6 days); however, these blocking agents are less effective than KI.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Insoluble Prussian Blue (Radiogardase®)

Prussian blue (insoluble ferric hexacyanoferrate) reduces the body burden of specific radionuclides by blocking uptake in the gastrointestinal tract followed by chelation/excretion of the radioisotope. Oral doses of 1–3 g of ferric ferrocyanide t.i.d. (Prussian blue) accelerate the removal of cesium, rubidium, and thallium from the gastrointestinal tract. The typical daily oral dose for adults and adolescents is 3 g t.i.d., whereas the daily dose for children 2–12 years of age is 1 g t.i.d. This compound has low toxicity with little absorption from the GI tract. Prussian blue is not a prophylactic agent.

Aluminum Hydroxide

The NCRP-preferred treatment for internal contamination with ^{226}Ra and ^{90}Sr is aluminum hydroxide (60–100 mL totaling 1,200 mg PO for adults and 50 mg/kg PO for children, not to exceed the adult dose), whereas barium sulfate (100–300 g PO as a single dose in 250 mL water) is a NCRP-suggested treatment. The dose should be administered within 24 hours of intake to block intestinal absorption. Additional NCRP-suggested treatments may include sodium alginate and calcium phosphate for internal radium contamination, calcium gluconate and barium sulfate for strontium inhalation, and stable strontium compounds (strontium lactate, strontium gluconate) for strontium ingestion.

Potassium Perchlorate

^{99m}Tc is a long-lived radionuclide that concentrates in the thyroid, salivary gland, lactating breast, and to a lesser extent in the alimentary tract, liver, and stomach, usually in the form of pertechnetate ($^{99}TcO_4^-$). In contrast to iodide, stable iodine (^{127}I) displaces pertechnetate in the thyroid and salivary glands; subsequently, pertechnetate does not bind organically for months in the thyroid. The NCRP recommends the use of potassium perchlorate to block the uptake of ^{99m}Tc by the thyroid gland.[72]

Diluting Agents

Dilution with water reduces tritium absorption by competing for the uptake of tritium. The administration of 3–4 L of fluid daily for 1 week with diuretics as needed reduces the biological half-life of tritium from 10 days to ~5 days.[29] The typical course of treatment is at least 3 weeks. Phosphate solutions (sodium, potassium salts, sodium glycerophosphate) function as diluting agents following excessive intake of ^{32}P. *Displacement therapy* refers to a type of dilution therapy (e.g., the use of calcium for the incorporation of ^{90}Sr) involving the competition for uptake into an organ (e.g., bone) between a stable element and a radionuclide of a different atomic number.

Enhanced Clearance

Indications for administering methods to enhance radionuclide excretion involve estimated radiation doses to critical organs exceeding values associated with adverse deterministic (nonstochastic) effects.

Chelation

Chelating agents bind metals in the extracellular fluid to form relative stable unionized ring complexes eliminated through the urine. Once radionuclide uptake into tissue occurs, the effectiveness of chelating agents decreases substantially. The primary chelator for radionuclides is diethylenetriaminepentaacetic acid (DTPA); this agent is available in the United States as the zinc and calcium salts from the US Strategic National Stockpile through the Oak Ridge Associated Universities, Radiation Emergency Assistance Center/Training Site (REAC/TS, general information 865-576-3131865-576-1005 after hours) Center, Oak Ridge Tennessee. The US FDA approved the intravenous use of DTPA for known or suspected internal contamination with three radionuclides (Am, Cm, Pu). Nebulization of DTPA is approved for adults exposed via inhalation.

Diethylenetriaminepentaacetic Acid (DTPA)

This compound effectively chelates the transuranium metals (plutonium, californium, americium, curium, berkelium), some transition metals (zirconium, niobium), and some rare earth metals (yttrium, promethium, lanthanum, scandium, cerium). The use of chelation for uranium exposure is not recommended because potentially excessive renal exposure to uranium may increase uranium-induced renal dysfunction, particularly when the systemic circulation contains >3 mg U, unless other chelatable radionuclides (e.g., plutonium) are present in sufficient concentrations to cause tissue damage.[29,73] Comprehensive support for the emotional needs of the patient undergoing chelation is an important aspect of the treatment program because treating patients with incorporated radionuclides frequently requires extended periods of isolation from their support systems. Figure 41.1 displays the chemical structure of diethylenetriaminepentaacetic acid (DTPA).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

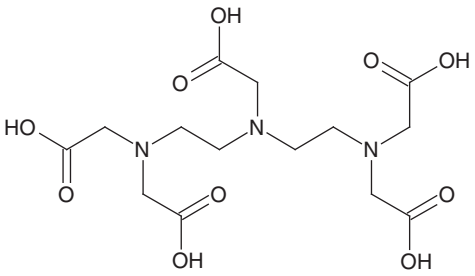

FIGURE 41.1. Chemical structure of diethylenetriaminepentaacetic acid (CAS RN: 67-43-6, DTPA).

Indications Clinical use of Ca-DTPA and Zn-DTPA primarily involves treatment of exposure to plutonium and americium at nuclear weapons or nuclear fuel processing facilities. The US distributor for DTPA is Golden State Medical Supply (https://gsms.us, 805-477-9866, Camarillo, CA). Rodent studies suggest DTPA is more effective at removing plutonium and americium than its lipophilic derivative Puchel (CAS RN: 75977-88-7)[74] or the sodium salt of N^1, N^5, N^{10}, N^{14}-tetrakis(2,3-dihydroxy-4-carboxybenzoyl)-tetra-azatetradecane (code name, 3,4,3-LICAM-C).[75] Animal studies also suggest Ca-DTPA is more effective than Zn-DTPA when administered promptly (i.e., several hours) to rats after exposure to ^{252}Cf, ^{239}Pu, and ^{241}Am.[76] Table 41.14 lists the NCRP-recommended uses of DTPA for chelation of absorbed radionuclides.

Dosage The initial recommended adult daily dose for both salts is 1 g DTPA as a single dose diluted in 250 mL normal saline and infused IV over 30 minutes. An alternative is the direct intravenous injection of 1 g of DTPA diluted in 10–20 mL of saline over 5 minutes. Extravasation of this solution may cause tissue necrosis.

TABLE 41.14. Diethylenetriaminepentaacetic acid, calcium or zinc salt (Ca-DTPA, Zn-DTPA) recommendations for chelation therapy of internal contamination by radionuclides based on National Council on Radiological guidelines.in NCRP Report 161.[72] Few clinical data are available to guide treatment decisions necessitating expert consultation (REAC/TS, medical toxicologist, RITN). The US Food and Drug Administration approved the use of DTPA for internal americium, curium, or plutonium contamination. The separate treatment recommendations in preferred and considered columns for treatment depend on the severity of exposure and medical evidence. The NCRP also considers DTPA the preferred treatment for other radionuclides of heavy metals including chromium, manganese, zinc, and zirconium.

Radionuclide	DTPA Treatment Recommendation	Other Potential Chelators
Actinium (Ac)	Considered

Administration of Ca-DTPA is recommended as soon as possible because chelation with radionuclides does not occur immediately after diffusion into tissues.[77] Ca-DTPA may be administered via nebulization in a 1 g dose over 15–20 minutes; the zinc salt produces a metallic taste. Because Zn-DTPA is less toxic than Ca-DTPA in experimental animals and depletes less Zn from the body, Ca-DTPA is usually administered during the first 24–48 hours, followed by long-term treatment with Zn-DTPA.[78] The exception is the initial treatment of pregnant women with Zn-DTPA. Animal studies suggest DTPA is more effective for water-soluble (e.g., chloride, nitrate) than water-insoluble (e.g., oxide) uranium compounds.[79] The duration of chelation by DTPA depends on the chemical form of the radionuclide. The uptake of some soluble complexes (e.g., plutonium nitrate) is rapid. DTPA effectively removes this complex from the blood; however, uptake of the relatively insoluble plutonium oxides is slow. Only small amounts of these complexes reach areas in the body where chelation can occur.

Pharmacokinetics DTPA absorption from the gastrointestinal tract is low (i.e., 3–5%); however, systemic absorption following parenteral administration is rapid.[80] The bioavailability of DTPA delivered by nebulization is ~20–30%. Following intravenous administration in the rat, the biological half-life of DTPA in the blood was 20–40 minutes; excretion occurred almost exclusively by glomerular filtration. Up to 75% of the chelate administered by inhalation appeared in the feces unabsorbed.

Adverse Reactions Generally, DTPA chelation is well tolerated;[77] the US DTPA Registry at the Radiation Emergency Assistance Center/Training Center (REAC/TS) reported no serious or long-term sequelae following parenteral administration.[80] Minor adverse reactions include nausea, diarrhea, skin rash, and pain near the injection site. Ca-DTPA binds trace minerals (e.g., zinc, manganese); in animal models, Ca-DTPA doses 100 times the recommended human dose produced hepatorenal lesions.

Other Chelating Agents

The efficacy of chelation is similar for isotopes and metallic forms of individual metals with limited clinical experience to determine the effectiveness of the therapy. Other potential chelating agents include sodium 2,3-dimercaptopropane-1-sulfonate or DMPS/unithiol (lead, mercury, polonium), penicillamine (copper, gold), and deferoxamine (iron). The decision to treat internal contamination with chelating agents involves careful consideration of the benefit of removing internal radioactive contaminants considering effectiveness and potential adverse effects compared with the risk of short- and long-term health effects from incorporation of the internal radiation dose without treatment. Table 41.15 lists the recommendations of the National Council on Radiological Protection and Measurements (NCRP) for chelating agents other than DTPA.

Bronchoalveolar Lavage

Lung lavage is a seldom-used experimental technique for removing large doses of long-acting, poorly soluble,

TABLE 41.15. NCRP treatment recommendations for chelating agents other than DTPA. Few clinical data are available to guide treatment decisions necessitating expert consultation (REAC/TS, medical toxicologist, RITN). Information on the efficacy of chelation of these isotopes is also available under individual metals.[72]

Radionuclide	NCRP Treatment Recommendation	Other Potential Chelators
Antimony (Sb)	BAL	Penicillamine
Arsenic (As)	BAL	DMSA
Bismuth (Bi)	DMSA	BAL, penicillamine
Cadmium (Cd)	DMSA	DTPA, EDTA
Copper (Cu)	Penicillamine	EDTA, trientine

inhaled α-emitting radionuclides (e.g., plutonium) deposited in the lungs; however, there are few data to determine the role of bronchoalveolar lavage and the efficacy of this procedure to reduce radiation pneumonitis and fibrosis. Lung lavage typically requires anesthesia. Animal studies using endotracheal intubation suggest 10 lung lavages with normal saline spaced 3–7 days apart remove ~25–50% of insoluble, inhaled particles.[81,82] The decision to use this procedure requires careful assessment of the risks of general anesthesia and potential benefits of bronchoalveolar lavage in consultation with radiation experts (e.g., Radiation Emergency Assistance Center/Training Center – REAC/TC, medical toxicologist, Radiation Injury Treatment Network or RITN). Consideration of this procedure usually occurs only when the estimated radiation dose from an α-emitting radionuclide is sufficient to produce radiation pneumonitis and fibrosis. Techniques to reduce gastrointestinal absorption may be necessary if the radionuclide can diffuse across the gastrointestinal mucosa after clearance from the tracheobronchial tree and secondary deglutition.

INDIVIDUAL RADIONUCLIDES

AMERICIUM

PHYSIOCHEMICAL PROPERTIES

^{241}Am is the most abundant isotope of the 13 americium isotopes resulting from the β-decay of ^{241}Pu. Table 41.16 lists the physical properties of the two most common americium isotopes (^{241}Am, ^{243}Am). The α-decay of ^{241}Am produces an X-ray with an energy of 60 keV (40% of the disintegrations). ^{243}Am is the only other americium isotope produced in significant quantities. The most important stable oxidation state in biological systems is the trivalent form.[83] These isotopes form weak complexes with components of the blood; hydrolysis and formation of americium and plutonium complexes are similar. Americium and curium oxides are more soluble than plutonium oxides; the former exists in the body exclusively in the trivalent oxidation state.

EXPOSURE

^{241}Am is one of the radionuclides released from anthropogenic sources (e.g., nuclear fission products, uranium–plutonium fuel cycle); this radionuclide is a constituent of some smoke detectors and thickness/density gauges. For the general population, the retention of this radionuclide from anthropogenic sources is usually small, including fallout from nuclear fission products and fuel components.[1] All plutonium contains some ^{241}Am from the neutron interactions of ^{241}Pu incompletely separated from ^{238}Pu or ^{239}Pu. The latter contains 15% ^{241}Am by activity.

TOXICOKINETICS

The main entry route for americium is inhalation or wound absorption. Absorption of ^{241}Am by the gastrointestinal tract is low (i.e., ~5%), whereas pulmonary absorption of most americium complexes is moderate. Urine samples from volunteers indicate the gut transfer factor (f_1 values) for americium in cockles ranges up to 2.6×10^{-4} with an arithmetic mean of 1.2×10^{-4}.[84] The toxicokinetics of americium and plutonium differ. The initial clearance is more rapid for americium than plutonium oxides, with the initial americium oxide half-life of 11–28 days; for modeling purposes, the IRCP inhalation model uses class W (weeks). In human studies, most

americium oxides deposited in the lungs have half-lives of tens of days, with the remainder having retention half-lives of months to years.[85] Retention of ^{241}Am in the ribs complicates the analysis of long-term ^{241}Am retention in the body. The major sites of deposition are the liver and bones with long effective half-lives of 2–3 years and >20 years, respectively.[1,86] These sites account for ~50% and 30% of the ^{241}Am incorporation, respectively, with the remainder divided into other organs (e.g., kidney, spleen) based on the IRCP model. Case reports suggest that experimental kinetic data do not fit well with the ICRP multiparameter models, including the type M model for acute americium inhalation. In contrast to prediction of the model, urinary americium excretion was not detectable after the estimated intake of ~200 Bq of $^{241}AmO_2$ powder using fecal sampling and monitoring (lung, whole body).[87] A 76-year-old man died of preexisting coronary artery disease 11 years after a massive ^{241}Am cutaneous exposure requiring 4 years of chelation; the estimated ^{241}Am deposition at autopsy was 540 kBq with 90% in the bones, ~5% in the liver, and 3.5% in the muscle/fat.[88] The highest soft tissue concentrations occurred in liver (22 Bq/g), larynx (15 Bq/g), and red marrow (9.7 Bq/g).

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In the Hanford worker contaminated with ^{241}Am, pathological findings at autopsy revealed markedly decreased bone marrow cellularity associated with dilatated blood sinusoids.[89] Damage was greatest on bone surfaces, particularly the almost acellular vertebra bodies with extensive bone marrow peritrabecular fibrosis in the ribs and clavicle. This patient underwent aggressive chelation with DTPA to reduce the liver burden and prevent liver failure. Animal studies indicate mice develop liver, bone, and hematological cancers following chronic intraperitoneal, inhalation, and injection.[1]

CLINICAL RESPONSE

An explosion in the ion exchange column containing nitric acid and essential pure ^{241}Am at the Hanford, Washington, nuclear weapons site contaminated a 64-year-old worker with >5,000 μCi of ^{241}Am; the internal ^{241}Am deposition exceeded occupational standards >1,000-fold. The cumulative absorbed radiation doses calculated after his death from preexisting cardiovascular disease 11 years postaccident were 18 Gy to the bones, 520 Gy to the bone surfaces, 8 Gy to the liver, and 1.6 Gy to the lungs.[90] Radiation-induced damage primarily involved lymphopenia and thrombocytopenia with an initial nadir of the lymphocyte count 7 days postexposure (530 lymphocytes/mm^3) and cytogenic changes in the lymphocytes;[91] Zn-DTPA chelation began 2.5 hours after exposure and continued over 2 years.[92] The IARC concluded there is sufficient evidence in experimental animals for carcinogenicity of mixed α-emitters including americium.[1]

TREATMENT

Intravenous Ca- and Zn-DTPA (diethylenetriaminepentaacetic acid, USFDA-approved since 2002) effectively chelate americium and several other transuranium ions (berkelium, curium, californium, plutonium);[93] clinical experience with these chelating agents primarily involves treatment of internal contamination with plutonium and americium. Nebulized DTPA is an option for chelating inhaled ^{231}Am depending on the level of contamination in the nares and the absence of pulmonary disease (e.g., asthma).[73] Both animal experiments and clinical experience confirm the prompt and prolonged use of DTPA as the chelating agent of choice. Therapy with DTPA should begin as soon as possible (i.e., ideally within a few hours), because even extended and intensive chelation therapy does not remove americium bone deposits.[94] Weekly chelation with DTPA over 30 months removed about half of the total-body americium burden, primarily from the lungs and liver in a man exposed over several years to ^{241}Am; however, the bone deposits were relatively unaffected.[95] Ca-DTPA is the chelating agent of choice during the first 24 hours of internal americium contamination because Ca-DTPA is more effective than Zn-DTPA during this time. After this time, both DTPA preparations are effective with the latter depleting zinc, magnesium, and manganese body stores significantly less than Ca-DTPA; clinical experience with Zn-DTPA indicates this chelator has a good safety profile during long-term therapy (e.g., 2 years).[96] In addition to trace metal depletion, other potential adverse effects include headache, lightheadedness, nausea/diarrhea, chest pain, allergic reactions, dermatitis, and local tissue reactions.

Suggested guidelines for initiating DTPA treatment for ^{241}Am nitrate and dioxide exposures include consideration for estimated internal doses of 20–200 mSv and implementation of treatment at doses exceeding 200 mSv.[93] The recommended initial Zn-DTPA dose is 1 g IV, followed by daily 1 g doses. The initial nebulized dose of Ca-DTPA is 1 g in 10 mL normal saline

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

via standard nebulizer with the switch to the intravenous route dependent on the decrease in lung burden and corresponding increase in systemic absorption of ^{231}Am from the lung. The duration of treatment depends on the amount of internal contamination and the response of the patient based on monitoring radioactivity by weekly blood, urine, and fecal samples. Indication for treatment varies between organizations depending on the estimation and uncertainties of the absorbed radiation dose. Guidelines for soluble and moderately soluble chemical forms in adults include considering the initiation of chelation when the estimated committed effective dose is 20–200 mSv and definitely implementing treatment when the dose exceeds 200 mSv.[93]

CALIFORNIUM

PHYSIOCHEMICAL PROPERTIES

Californium is a member of the actinide series; the most common of the 13 isotopes (242–254) is ^{252}Cf. The latter has a unique pattern of decay with emission of a 6.12 MeV α-particle and a fission fragment; spontaneous emission of 3.8 fast neutrons results from each fission. The fragment accounts for ~50% of the total decay energy. ^{249}Cf decays by emitting α-particles and smaller amounts of γ-radiation. The decay energy/disintegration of ^{249}Cf is ~½ of ^{252}Cf.

EXPOSURE

^{252}Cf primarily is a neutron source. An encapsulated source of ^{252}Cf is substituted for radium in intracavitary and interstitial applications in radiotherapy. In industry, applications include neutron excitation in nuclear reactors, neutron activation analyses, neutron radiography, and neutron diffraction measurements.[25]

TOXICOKINETICS

Absorption of ^{252}Cf occurs primarily from the lungs and open wounds because intestinal absorption is negligible.[97] Retention, disposition, and distribution of californium and americium are similar, whereas the biological half-life of ^{252}Cf is 175 years and the effective half-life is 2.2 years. Deposition occurs quickly in the skeleton. The principal means of detecting internal contamination with ^{252}Cf is monitoring the urine for α-particles.[98] Following an initial half-life of 1 day and the initiation of chelation therapy, urinary elimination half-lives ranged from 10–12 days in two workers contaminated by inhaled californium oxide.[99]

CLINICAL RESPONSE

Although data on human carcinogenicity are few, the IARC states there is *sufficient evidence* in experimental animals for the carcinogenicity of mixed α-particle emitters including ^{249}Cf and ^{252}Cf.[1]

TREATMENT

Because of the lack of human data, treatment is based primarily on animal data. Treatment with Ca-DTPA should begin immediately to rapidly reduce deposition of ^{252}Cf in the bone; this chelator is USFDA-approved for the treatment of internal contamination by ^{252}Cf. Once deposition occurs, removal of significant amount of ^{252}Cf is difficult; however, animal experiments suggest removal continues 3 weeks after the intravenous administration of ^{252}Cf.[100]

CERIUM

PHYSIOCHEMICAL PROPERTIES

Cerium is one of the lightest (atomic number 58) members of the lanthanide group of elements that range in atomic number from 57–71. Of the 20 cerium isotopes with masses of 129–148, the 4 naturally occurring isotopes are ^{136}Ce, ^{138}Ce, ^{140}Ce, and ^{142}Ce. The most important radioisotopes are the β-emitters, ^{141}Ce, ^{143}Ce, and ^{144}Ce; these radionuclides are released abundantly in nuclear fission reactions with relatively long half-lives and could potentially cause prolonged retention in the body.

Table 41.17 lists the decay products of the important cerium isotopes. Insoluble cerium complexes include carbonates, potassium sulfates, oxalates, aluminosilicates, and oxides, whereas chlorides and citrates are relatively soluble cerium complexes. Because of the limited solubility of hydroxides, lanthanides do not exist as ions at physiological pH.

EXPOSURE

The primary sources of cerium radionuclides were relatively insoluble chemical complexes (e.g., oxides) of ^{141}Ce, ^{143}Ce, and ^{144}Ce released from nuclear explosive

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 41.17. Radioactive decay chains of cerium radioisotopes with half-lives of 17 hours–284 days. All these isotopes are considered stable except 137 (half-life 60,000 years); however, the half-life is sufficiently long to be considered stable for radiation dosimetry. (Adapted from National Council on Radiation Protection and Measurements).[101]

Isotope	Half-Life	Decay Mode	Decay Product	Decay Product Half-Life	Decay Mode	Decay Product
^{134}Ce	3 days	Electron capture	^{134}La	6.7 minutes	β^+	^{134}Ba
^{135}Ce	17 hours	Electron capture	^{135}La	19.5 hours	Electron capture	^{135}Ba
^{137}Ce	34 hours	Isomeric transition	^{137}Ce	9 hours	Electron capture	^{137}La
^{139}Ce	140 days	Electron capture	^{139}La			
^{141}Ce	32.5 days	β-particle	^{141}Pr			
^{143}Ce	33 hours	β-particle	^{143}Pr	13.6 days	β	^{143}Nd
^{144}Ce	284 days	β-particle	^{144}Pr	17.3 minutes	β	^{144}Nd

devices and nuclear power facilities. The most likely exposure sources now are nuclear fuel reprocessing plants and test reactors. The annual production of ^{144}Ce from a nuclear power facility is 5.3 kg/1,000 MW of electric power.[101] Uranium fission produces radioactive cerium isotopes; however, the relatively short half-lives compared with ^{144}Ce limit the abundance of these isotopes in radioactive waste. Industrial cerium sources include photoengraving, glass manufacturing, optical lens polishing, industrial thickness/flow gauges, radiotherapy units, and carbon arc lamp production. The low volatility and solubility of cerium compounds in aqueous solvents restrict their flow through the biological food chain.

TOXICOKINETICS

The gastrointestinal absorption of cerium compounds is low ($<10^{-3}$) in adults, whereas inhalation of ^{144}Ce/^{144}Pr from the air has intermediate solubility and is the major exposure route similar to results from experimental studies of other cerium forms (e.g., $^{144}CeCl_3$, $^{144}Ce(OH)_3$, $^{144}CeO_2$).[1] Animal studies indicate gastrointestinal absorption of soluble Ce forms is much greater for neonates than adults. The liver and bones are the primary sites of deposition following Ce absorption. The deposition fractions are ~0.45–0.50 and ~0.30–0.35, respectively, with 0.10 of the absorbed dose deposited in soft tissue and the remainder excreted in feces and urine.[101,102] The hepatic and skeletal retention times are sufficiently long that the effective biological half-life of cerium is equivalent to the physical half-life. Following an accidental exposure of a worker to ^{144}Ce during the grinding of uranium metal, the effective and physical half-lives of ^{144}Ce in the lung were similar (i.e., 280 days).[103] The effective half-lives of cerium in the liver and bones were also indistinguishable from the physical half-life, despite having biological half-lives measured in thousands of days. ^{144}Ce is a bone surface seeker that deposits on surfaces of the trabecula, periosteum, articular cartilage, and vessels of the diaphysis.

CLINICAL RESPONSE

Relatively soluble ^{144}Ce compounds transfer rapidly from the lungs and deposit in the liver and skeleton. The liver is the primary target organ for the shorter-lived cerium isotopes, whereas the bone is the critical organ for the longer-lived isotope, ^{144}Ce. Hence, health effects in the lungs are minimal with late effects (e.g., myeloproliferative diseases, hepatic fibrosis, liver and nasal cavity cancers, osteosarcomas) developing in animals after long latency periods. Relatively insoluble ^{144}Ce compounds produce effects primarily in the lungs and tracheobronchial lymph nodes, depending on the internal radiation dose. Case reports associate the development of a pneumoconiosis with long-term pulmonary exposure (i.e., >15 years) to cerium oxide;[104,105,106] these case reports involve workers (e.g., photoengravers, glass polishers) exposed to natural cerium isotopes rather than cerium radioisotopes.

The IARC lists ^{144}Ce and its decay products as an animal carcinogen based on sufficient evidence in experimental animals for the carcinogenicity of mixed β-particle emitters (i.e., ^{144}Ce). Inhaled insoluble ^{144}Ce produced lung tumors in mice, rats, Syrian hamsters, and dogs, whereas dogs developed lung, liver, bone, and hematopoietic neoplasms following chronic inhalation of soluble ^{144}Ce. There are few data on the human carcinogenicity of ^{144}Ce. Pulmonary hemangiosarcomas are rare neoplasms that occur frequently in animals exposed to insoluble forms of ^{144}Ce.[107]

TREATMENT

Animal studies suggest that chelation with DTPA should begin as soon as possible for rare earth metals,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

even though the specific protocols for DTPA do not list exposure to rare earth metals as an indication for chelation therapy. The effectiveness of DTPA therapy depends on the prompt initiation of therapy and the solubility of the cerium compound in the lung.[108] In rodent studies, the efficacy of DTPA depended on the time of administration after internal contamination, ^{144}Ce distribution in organs, and maturity of the body.[109] The treatment of ^{144}Ce contamination is usually supportive; the use of DTPA is not typically recommended for ^{144}Ce contamination.

CESIUM

PHYSIOCHEMICAL PROPERTIES

Cesium is a silvery white, soft, ductile metal with one oxidation state (+1) and a relatively low melting point (28°C/82°F); this metal is a highly water-soluble alkali metal that has 21 radioactive isotopes. Both ^{134}Cs and ^{137}Cs produce β-particles and γ-rays during disintegration. The physical half-life of ^{137}Cs is ~30 years, decaying by β-decay either to stable ^{137}Ba or a meta-stable form of barium (^{137m}Ba) that almost immediately converts to stable ^{137}Ba after emission of a γ-ray (0.662 MeV). ^{134}Cs decays primarily to stable ^{134}Ba by β-decay and emission of a γ-ray or less frequently to stable ^{134}Xe by electron capture along with emission of a single γ-ray. Cesium, rubidium, and potassium are chemically similar, blocking most K^+-selective channels. Although cesium competes with potassium for transport through potassium channels, the cesium movement through these channels is much slower than potassium.[110]

EXPOSURE

Cesium exists naturally in the earth's crust as the stable isotope ^{133}Cs, typically at concentrations of 1 ppm (in granite) to 4 ppm (in sedimentary rock).[111] Pollucite (5–32% CsO_2) is the most commercial cesium source. In industry, ^{137}Cs is used as a sealed source of γ-rays for machines that measure the thickness of materials, whereas ^{137}Cs is a tracer substance in imaging procedures and a sealed source for radiotherapy. Nuclear fission in commercial applications (e.g., nuclear power plants) and nuclear weapons testing produce the main radioactive cesium isotopes (^{134}Cs, ^{137}Cs). Routine maintenance and production of electricity at nuclear power plants produce clinically insignificant amounts of radioactive cesium isotopes.[111]

ENVIRONMENTAL FATE

Air

Prior to the accident at Chernobyl, most ^{137}Cs deposited in humans resulted from nuclear fallout from weapons testing. Following release to the atmosphere, radioactive cesium can travel thousands of miles before removal by wet and dry deposition. The persistence of radioactive cesium isotopes in the environment is long. Based on fallout from the Chernobyl nuclear reactor accident, the half-life of ^{137}Cs is 2–4 years on urban surfaces (e.g., asphalt) and 3–15 years on park lawns, sand walkways, and forested areas.[112]

Soil

Cesium demonstrates very low mobility in soil surfaces, particularly in potassium-rich clay soils that bind cesium; cesium absorption by grasses and other plants is limited.

Diet

Ingestion of contaminated food items is the greatest source of internal exposure for both naturally occurring and radioactive cesium. ^{137}Cs enters the food chain when plants absorb contaminated rain, thereby transferring this radionuclide to the food chain. Milk and meat account for about 60–80% of the total intake. Other potential sources include nuclear processing plants for persons near these facilities; however, current cesium levels are usually well below the levels present from natural radiation.[113,114] Fungi enhance the mobilization of radiocesium from natural soils, increasing the transfer of this radionuclide to the food chain.[115]

TOXICOKINETICS

Absorption

Soluble cesium compounds are almost completely absorbed by the lung and the gastrointestinal tract. In a study of 10 volunteers ingesting venison containing ^{134}Cs and ^{137}Cs, the estimated uptake of radiocesium ranged from 65–90% (mean = 78%).[116] A simulated study of ^{137}Cs absorption from radioactive fallout particles collected following a land-surface detonation and administered in a gelatin capsule to 10 volunteers suggests cesium contained within the fallout is relatively insoluble and poorly absorbed in the gastrointestinal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tract (i.e., ~3%).[117] In this study, the gastrointestinal absorption of soluble cesium as a tracer (^{134}CsCl) by four volunteers was relatively complete (i.e., ~90%).

Distribution

Following absorption, cesium disseminates easily throughout the body as a potassium analog and no specific organ accumulates a disproportionate amount of cesium. The erythrocyte/plasma ratio is variable depending on the time after exposure. Case reports suggest this ratio varies from ~3.5 soon after exposure to 14 one month after exposure.[118]

Elimination

There is wide variability in the retention of radiocesium depending on a variety of factors including age, muscle mass, sex, and potassium content. Biokinetic modeling suggests ^{137}Cs follows a two-compartment exponential model with fast and slow components. The mean biological half-life of ^{137}Cs is ~70–110 days with about 10% rapidly eliminated with a half-life of 2 days.[117,119] Following the ingestion of venison containing ^{134}Cs and ^{137}Cs, the mean biological half-life of radiocesium was 90 ± 50 days with a range of 45–210 days.[116] In a study of two workers exposed to airborne $^{137}CsSO_4$ and followed for 285 days, the biological half-time for the two workers was 73 days and 84 days, respectively.[120] Based on a two-exponential model, the long-term biological half-time of ^{137}Cs in a worker accidentally exposed to radiocesium after the explosion of an ampule containing ^{137}cesium chloride was ~93 days.[121] The terminal half-life for <1% of ^{137}Cs is longer (i.e., ~500 days). Excretion occurs primarily through the urine.[122]

Maternal-Fetal Kinetics

^{137}Cs is excreted in breast milk based on studies of breastfeeding women living in areas contaminated with radioactive fallout from the Chernobyl nuclear accident. Analysis of whole-body measurements of radioactivity in 12 Swedish mothers and nursing infants (6–12 months old) measured radioactivity in breast milk samples and estimated that 15% of the mothers' daily ^{137}Cs intake from contaminated food was transferred to the infant.[123] The estimated absorbed doses for a newborn baby and a 1-year-old child relative to the maternal doses were ~40% and ~50%, respectively.

Clinical Response

Radiocesium

Accidents resulting from industrial, medical, and research uses of ^{137}Cs are relatively uncommon, with complications ranging from skin damage to radionecrosis of the femoral arteries requiring bilateral amputations.[45] Accidental exposure of Russian military recruits to a sealed source of ^{137}Cs caused symptoms typical of cutaneous radiation syndrome manifested by initial dermal erythema, followed by well-demarcated ulceration, hypopigmented, hairless macules, and subsequent hyperpigmentation.[124] Some of these recruits also complained of nausea, vomiting, and headache. On September 13, 1987, in Goiania, Brazil, two scavengers removed a shielded radioactive ^{137}Cs chloride source containing ~51 TBq (1,375 Ci, mass of ~100 g) from its protective housing in an abandoned clinic; they transported the unshielded source to their home for eventual sale to a junkyard. The source container was ruptured with the contents widely distributed from fascination with the blue luminosity of the ^{137}Cs. Over the next 2 weeks, extensive dissemination occurred through social contacts with contaminated individuals and the sale/transfer of contaminated material from two junkyards. The radioactivity of the source was discovered after the wife of the junk man transported the source to the Sanitary Surveillance Division after she suspected an association between the development of gastrointestinal illness in her acquaintances and exposure to the source.

The severity of the radiation illness and the number of people affected were second only to the injuries caused by the Chernobyl incident. Of the 250 people in Goiania exposed to ^{137}Cs, at least 14 displayed signs of bone marrow suppression and 8 individuals developed symptoms of the hematological phase of the acute radiation syndrome.[125] Four people died within the first month from bleeding and sepsis secondary to resistant *Klebsiella* species.[126] Internal contamination occurred in 104 patients. None of the victims displayed evidence of the gastrointestinal or CNS phase of the acute radiation syndrome.

Local radiation injuries included 7 first-degree burns (estimated dose of 5 Gy), 15 second-degree burns (estimated dose of 12–20 Gy), and 6 third-degree burns (estimated dose >25 Gy).[45] The rapid onset of erythema identified the most seriously burned patients. Significant ulceration developed without a latent period following the erythematous phase in patients with third-degree burns. Burning pain, hypoesthesias, pruritus, and paresthesias were the most common

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. complaints. Most of the injured areas regenerated a thin, atrophic, fragile epithelium by 3 months. Depigmentation in dark-skinned patients and hyperpigmentation in light-skinned patients occurred following regeneration of the skin. Atrophy and sclerosis of underlying tendons, tendon sheaths, and cartilage complicated the recovery of hand injuries.

Stable Cesium

Exposure to toxic cesium concentrations is associated with cardiovascular complications. A case report suggests that chronic use of cesium may produce magnesium and potassium wasting.[127] These electrolyte changes may cause QT prolongation and serious ventricular dysrhythmias. QTc prolongation (683 msec), monomorphic ventricular tachycardia, and syncope developed in a 16-year-old girl after starting an alternative treatment regimen involving cesium chloride.[128] These abnormalities may occur in the absence of serious electrolyte depletion from the inhibition of potassium rectifier channels. A case report associated the development of QTc prolongation (QTc = 620 msec) and *Torsades de pointes* with the use of nonradioactive cesium (^{133}Cs) chloride as an unproven alternative treatment for cancer.[129] The serum potassium concentration was 2.8 mEq/L, whereas the serum magnesium and calcium concentrations were normal.

Cesium Chloride

A 16-year-old girl with metastatic hepatocellular carcinoma developed stable cesium-induced QT-interval prolongation and syncope after starting an alternative treatment regimen including cesium chloride and a diet high in potassium, magnesium, and calcium.[128] She was admitted to the cardiac care unit after an episode of monomorphic ventricular tachycardia. Her plasma cesium concentration was 2,400 µg/dL with normal serum electrolyte concentrations. During follow-up 2 months later, her cesium concentration was 1,800 µg/dL (QTc = 494 msec).

Treatment

Oral insoluble Prussian blue (insoluble ferric hexacyanoferrate[II], Radiogardase™) is the preferred agent for de-corporation of patients contaminated with radioactive cesium based on the reduction of the biological half-life during treatment.[130] In a case report on nonradioactive cesium chloride toxicity, the use of insoluble Prussian blue enhanced the gastrointestinal elimination of cesium by reducing the serum cesium half-life from 61.7days to 29.4 days during 4 weeks of therapy (total amount excreted was not reported).[129] When initiated promptly after internal contamination, administration of insoluble Prussian blue reduces absorption and disrupts the enterohepatic recirculation of cesium. The increased fecal cesium elimination decreases the total-body cesium burden by a factor of 2–3.[131] The *in vitro* binding characteristics of ^{137}Cs suggest the insoluble form of Prussian blue ($Fe_4[Fe(CN)_6]_3$) is more effective than the soluble form ($K_3Fe[Fe(CN)_6]$) because the soluble form decomposes to $[Fe(CN)_6]^{-4}$; the latter reacts with ^{134}Cs to limit excretion of this isotope in animal models.[132] In rats, 5 mg Prussian blue administered 2 minutes before ^{134}Cs decreases absorption of this tracer to 5–6% of control values.[133] Total daily doses ranging from 1–10 g of insoluble Prussian blue (ferric hexacyanoferrate[II], Radiogardase™) were administered in three equal doses during the day to patients at Goiania with internal contamination from ^{137}Cs.[134] Patients tolerated an initial daily dose up to 20 g of Prussian blue with only minor adverse effects (constipation, mild hypokalemia). In this group of patients, daily doses of >3 g of Prussian blue were efficacious in adults (pediatric dose age 2–12 years: 1 g three times daily), but the use of diuretics did not improve the elimination of ^{137}Cs from the body. Biokinetic modeling suggests Prussian blue reduces the long-term biological half-life of cesium when administered during the first year postexposure.[135]

Radiogardase™ is available through the Radiation Emergency Assistance Center in Oakridge, Tennessee (https://orise.orau.gov/reacts/resources/documents/radiogardase-package-insert.pdf). A fiber-based laxative and/or a high-fiber diet are recommended along with the administration of Prussian blue to prevent constipation and promote fecal cesium excretion. Patients should be monitored for electrolyte imbalances, particularly the serum potassium concentration. *In vitro* studies indicate that sodium polystyrene sulfonate, activated charcoal, and hemoperfusion probably would not improve the elimination of cesium from the body.[132]

COBALT

PHYSIOCHEMICAL PROPERTIES

The most important cobalt radioisotopes are ^{60}Co ($t_{½}$ = 5.27 years), ^{57}Co ($t_{½}$ = 272 days), ^{58}Co ($t_{½}$ = 70.9 days), and ^{55}Co ($t_{½}$ = 17.5 hours).[136] Decay of ^{60}Co occurs by the emission of β-particles and γ-rays, whereas ^{58}Co decays by electron capture or positron emission to ^{58}Fe.

EXPOSURE

Radioactive contamination from nuclear reactors, fuel-reprocessing plants, nuclear waste facilities, and laboratories may contain cobalt radioisotopes from neutron activation of impurities in reactor coolant system and fuel element cladding. ^{60}Co is the neutron activation product resulting from bombardment of stable ^{59}Co with neutrons; consequently, this radioisotope is a frequent radioactive contaminant in nuclear wastewater. ^{59}Co is a pure γ-ray source for medical therapy, commercial sterilization (medical equipment, food, spices, hot cells), and industrial radiography (structural flaws, thickness gauges, leveling devices).[137,138] ^{58}Co is also a radioactive contaminant of nuclear plants; Bleomycine-^{57}Co and $^{55}CoCl_2$ are diagnostic agents in nuclear medicine for brain imaging (i.e., brain trauma, multiple sclerosis, stroke). ^{55}Co-PET has relatively high spatial resolution/absolute quantitation but limited availability due to its short half-life; ^{57}Co-SPECT has wider availability but lower spatial resolution and a relatively high radiation dose. The estimated maximum doses of $^{55}CoCl_2$ and ^{57}Co are 0.5 mCi and 0.3 mCi, respectively, assuming 2% ^{56}Co contamination.[139] ^{55}Co is commonly produced by the ^{56}Fe(p,2n)^{55}Co nuclear reaction using target material, natural iron; consequently, ^{56}Co is always a long-lived contaminant of commercial ^{55}Co.[140]

TOXICOKINETICS

Absorption

The mean gastrointestinal uptake of inorganic forms of cobalt radioisotopes in human studies ranges from ~3–40%, depending on the solubility of the radioisotope. Typically, $^{60}CoCl_2$ uptake is <5% compared with <0.1–0.5% for ^{60}CoO;[136,141] however, whole-body counting studies suggest absorption of $^{60}CoCl_2$ may increase with increasing dose. In a study of 11 male volunteers, the gastrointestinal absorption of $^{60}CoCl_2$ increased from 5% following the ingestion of <1 μg to 20% after ingestion of 1.2 mg stable cobalt.[142] The absorption of more soluble organic cobalt forms is more complete.[143]

Elimination

In a study of 19 adult volunteers, the kidneys excreted an average of 30% (range, 14–47%) of an absorbed ^{58,60}Co dose with a urine/fecal excretion ratio of 6:1.[142] The initial biological half-life for ~80% of ^{60}Co is 1 day; however, the elimination half-life for the remainder is much slower (i.e., years), as demonstrated by long-term studies of accidently inhaled insoluble forms of ^{60}Co (e.g., cobalt oxide).[141] Following the inhalation of ~0.5 μCi of ^{60}Co dust during decontamination of ductwork, the initial biological half-life in three workers was ~1.6 days during the first week postexposure, while the half-life 17–50 days postexposure increased to 42 days and ~110 days 3 months after the initial exposure.[144] Fecal excretion accounted for 80–90% of the cobalt elimination with a maximum 2–3 days postexposure. During this time, urinary cobalt excretion accounted for 10–20% of the total Co excretion with 2/3 eliminated during the first day.

In a long-term study of a worker exposed to an aerosol of ^{60}Co from a hot cell at doses well below current occupational standards, the elimination of ^{60}Co followed the ICRP inhalation class W with an initial half-life ranging from 25–78 days and a terminal half-life of 500–1,100 days (mean ~900 days).[145] The initial elimination results from cobalt clearance from the lung that may be more prolonged following inhalation of insoluble forms of ^{60}Co than predicted by the ICRP model.[136] The predicted biological half-life for long-term clearance of class Y compounds is 500 days. In a case series of four power station workers exposed to ^{60}Co (i.e., cobalt oxide) via inhalation, the average biological half-life was 664 days.[146] Long-term clearance results from the systemic clearance of cobalt from the body stores (i.e., bone) rather than soft organs (e.g., liver).[147]

CLINICAL RESPONSE

^{60}Co is a potential source of high-dose γ-radiation capable of producing severe radiation sickness including alopecia, skin necrosis, loss of limb, and death.[148,149] The mishandling of a sealed ^{60}Co source resulted in the irradiation of a worker with an estimated nonuniform, whole-body dose of 1.2–1.6 Gy.[150] Initially, minor changes in the peripheral lymphocyte count, severe skin necrosis over the left hand, and epilation of a small area over the left temporal region occurred. Secondary defects in the skin of the left hand developed after 13 months eventually requiring amputation of all of the digits except the thumb. Initial changes in the lens of the left eye appeared 18 months after the accident and progressed to significant visual impairment.

The National Toxicology Program (NTP) lists cobalt and cobalt compounds that release cobalt ions *in vivo* as reasonably anticipated to be human carcinogens based on sufficient evidence from studies in experimental animals and supporting plausible mechanisms (e.g.,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

genotoxicity, oxidative damage from generation of reactive oxygen species, stabilization of hypoxia-inducible factor resulting in enhanced cancer cell survival in oxygen-deficient environments, inhibition of DNA repair).[151] However, evidence from human studies was inadequate to adequately evaluate or quantify the risk of cancer following exposure to cobalt and cobalt compounds that release cobalt ions. The IARC listed implanted foreign bodies of metallic cobalt as possibly carcinogenic to humans (Group 2B) based on sufficient evidence in experimental animals and inadequate data in humans.[152]

DOSIMETRY

Two workers in a Canadian nuclear power plant were irradiated with individual whole-body doses of 127.4 and 92 mSv during the removal of cobalt adjuster rods.[153] Serial lymphocyte counts and cytogenetic analysis did not demonstrate significant abnormalities as interpreted by three laboratories blinded to the samples and controls. The patients developed some stress-related symptoms but no signs or symptoms related to radiation exposure. Monitoring of a radiation accident involving an unshielded ^{60}Co source indicated that exposure to an estimated whole-body radiation dose of 150 mSv produced dicentric chromosomes within 2 months after the incident.[154]

Unstable chromosomal aberrations (i.e., dicentrics, rings, micronuclei) in peripheral lymphocytes demonstrate a dose-response relationship between ionizing radiation dose and the number of these abnormalities; however, the accuracy of these estimates declines substantially several months after acute radiation exposure.[155] Stable chromosomal aberrations (e.g., translocations, inversions, deletions) persist much longer. In a Chinese study of chromosomal aberrations in peripheral blood lymphocytes from five workers 1 day to 17 years after accidental exposure to 1.9–5.1 Gy of ^{60}Co γ-ray radiation, the frequency of unstable chromosomal aberrations (dicentrics and rings) remained constant one month after exposure.[156] By 3 months postexposure, the frequency of these aberrations decreased by 20–40% in three workers with the lowest radiation doses while remaining constant in two workers with the highest radiation dose. The number of unstable chromosomal aberrations decreased by 90% from initial values by 12 years postexposure without a dose-dependent relationship. Follow-up 17 years postexposure demonstrated the persistence of high levels of stable chromosomal aberrations (i.e., translocations) in a dose-dependent relationship.

TREATMENT

Several sources suggest potential chelating agents for cobalt radioisotopes, including DTPA, DMSA (Succimer), $CaNa_2EDTA$, and *N*-acetylcysteine, based on animal experiments; however, clinical experience is inadequate to determine the efficacy of these agents. The NCRP lists DTPA as the preferred chelator.[72] Although some case reports suggest chelation substantially reduces blood cobalt concentrations,[157,158,159] results are variable and difficult to compare with the natural course of blood cobalt concentrations without treatment. The role of chelation in the treatment of symptomatic patients with elevated concentrations of stable cobalt from malfunctioning metal hip implants also remains undefined other than hip replacement.

CURIUM

PHYSICOCHEMICAL PROPERTIES

Curium is a member of the transuranic radionuclide group (i.e., ^{237}Np, ^{239}Pu, ^{241}Am) emitting primarily α-particles. Both americium and curium oxides are more soluble than plutonium oxide. Of the 12 curium isotopes, only ^{242}Cm and ^{244}Cm are produced in significant amounts. In biological solutions, the trivalent form is the most stable oxidation state.[83] The high-specific activity of curium causes spontaneous heat production in addition to the emission of energetic α-particles, neutrons, and gaseous daughter products; consequently, serious radiation injury may occur from exposure to relatively small amounts of curium.[25] Table 41.18 lists some physical properties of ^{242}curium and ^{244}curium.

EXPOSURE

The main sources of transuranic radionuclides are thermal and breeder nuclear reactors, with ^{244}Cm

TABLE 41.18. Some physical properties of ^{242}curium (^{242}Cm) and ^{244}curium (^{244}Cm).

Physical Property	^{242}Curium	^{244}Curium
Radioactivity half-life (years)	0.447	17.9
Principal decay mode	α-particles	α-particles
Mean α-energy (MeV)	6.10	5.80
Specific activity (μCi/g)	3.31×10^{9}	8.20×10^{7}
Mass/μCi (g)	3.02×10^{-10}	1.22×10^{-8}
Relative mass[a]	1.85×10^{-5}	7.48×10^{-4}

[a] Mass relative to 1 μCi of ^{239}Pu set as 1.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

accounting for >90% of the curium isotopes produced in the nuclear cycle. Curium is present in thermoelectric generators, aerospace satellites, and transuranic production processes. ^{243}Cm and ^{244}Cm possess very high-power output/unit mass (W/g) resulting in their use as compact power sources due to the very large heat release per gram. The physical half-life of the longest-lived curium radionuclide (^{247}Cm) is short compared with the earth's age; little primordial curium remains in the earth's crust, except for minute amounts in natural uranium deposits.

TOXICOKINETICS

^{244}Cm is relatively soluble; therefore, this isotope is more easily absorbed than plutonium, whereas the kinetics of ^{242}Cm, ^{244}Cm, and ^{241}Am are similar.[160] The fractional absorption rate of curium isotopes from the gastrointestinal tract (f_1 value) is low (i.e., ~0.01–0.03%) based on human volunteer studies.[161] The lungs clear curium compounds more rapidly than plutonium complexes; limited data suggest the lung clears ^{244}Cm oxide in a few days during the first week postexposure followed by ~1 month afterward.[160] In contrast to plutonium, curium distribution in the lungs is relatively uniform. Most internally deposited curium appears in the bones (i.e., 80%) and the liver (i.e., 15%) with retention in the latter being specie-dependent. Insoluble chemical forms of curium may remain in the lungs, whereas the critical target organ for soluble curium compounds is the bones, where the effective half-life of ^{244}Cm is 16.7 years. Elimination rates of transuranic radionuclides are comparatively rapid. The biological half-life of ^{244}Cm is ~10 days with excretion occurring in the urine (~10%) and feces.[162]

CLINICAL RESPONSE

Few human data on the adverse effects of curium isotopes are available. Lung and/or bone tumors are the major health risks following the absorption of ^{242}Cm and ^{244}Cm.[160] The IARC classifies ^{244}Cm as an animal carcinogen based on experimental studies; human data are unavailable because of the rarity of curium contamination.

TREATMENT

DPTA is a USFDA-approved chelator for internal contamination by curium. Animal studies suggest the weak protein binding of curium enhances DTPA chelation.[83] The prevention of curium deposition in bone and liver requires administration of DTPA chelation soon after exposure (i.e., several hours). Ca-DTPA distributes rapidly throughout extracellular fluids without diffusing across cell membranes; almost complete Ca-DTPA excretion from the body occurs within 12 hours. The urine should be monitored to determine the amount of curium and evaluate the effectiveness of chelation. Ca-DTPA is the chelator of choice during the first 24 hours after internal contamination based on animal studies; Ca-DTPA is more effective for internal contamination with curium than Zn-DTPA during this initial time.[163] After the initial 24-hour period of internal contamination, both DTPA preparations are equally effective.

GOLD

Of the 24 radioactive isotopes of gold, only ^{198}Au is commonly used in biological research, radiotherapy, and industrial calibration. ^{198}Au emits 0.97 MeV β-particles and 0.41 MeV γ-rays with a physical half-life of 2.7 days. Absorption of noncolloidal ^{198}Au is limited to ~10% of the administered dose; elimination occurs by the kidney and feces. The intravenous administration of colloidal ^{198}Au results in radionuclide deposition in reticuloendothelial cells of the spleen, liver, bone marrow, and lymph nodes with an effective half-life of 2.6 days.[164] A patient mistakenly received a dose of 200 mCi of ^{198}Au intravenously; the estimated absorbed dose to the bone marrow was 440 rads.[25] He died 70 days after administration from thrombocytopenia with subsequent intracerebral hemorrhage. There are no data on the effectiveness of chelation therapy for ^{198}Au; however, dimercaprol and penicillamine are theoretical considerations for chelation.

IRIDIUM

Iridium exists naturally as an alloy with osmium (osmiridium), primarily in the tetravalent state in multicolored complex salts. This rare member of the platinum group has good electrothermal conductivity with a density of 22.56 g/cm^3, an atomic mass of 192.217, and a melting point of 2,466°C. ^{192}Ir is a γ-ray source for industrial radiography (i.e., radiography cameras) to inspect pipes, metal vessels, and defective welds. Although relatively rare, multiple industrial exposures to ^{192}Ir have occurred from the mishandling of these cameras, resulting in radiation dermatitis.[165,166] This radionuclide emits

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

β-particles and γ-rays with a physical half-life of 74 days; this isotope readily penetrates human skin. The intestinal mucosa absorbs ~1% of an orally administered dose. Inhalation of ^{192}Ir results in protracted retention (IRCP class Y) of ^{192}Ir; therefore, prolonged irradiation of pulmonary tissue occurs following inhalation. Most occupational ^{192}Ir exposures involve local skin damage rather than systemic effects, particularly to the hand.[167] Improper handling of an ^{192}Ir source resulted in permanent sequelae ranging from thin, sensitive skin[168] to local necrosis of the skin and deeper tissue layers; these changes potentially predispose the patient to frequent abscesses and brittle bones.[169]

Chronic radiodermatitis developed in a 26-year-old man several months after high-dose industrial exposure to ^{192}Ir and manifested by necrosis, sclerosis, and ulceration of the previously irradiated skin.[170] Initially, erythema, edema, vesiculation, and desquamation of the exposed skin may occur, which regress in several weeks; later, chronic radiodermatitis occurs with dark red hyperpigmentation, edema, and atrophy persisting in the necrotic areas for many years.[171] Although some sources suggest DTPA as a chelating agent for ^{192}Ir (e.g., the National Council on Radiation Protection and Measurements), insufficient animal and human data are available to determine the efficacy of DTPA following contamination with ^{192}Ir.

IODINE

PHYSIOCHEMICAL PROPERTIES

Of the 35 iodine isotopes (^{108}I–^{142}I), only ^{127}I is stable with the rest being radioactive. Approximately half of these isotopes are fission products of nuclear reactors with most of these having half-lives of <≤1 minute. Some radioactive isotopes have half-lives ranging from 1–6.7 hours (e.g., ^{132}I, ^{133}I, ^{134}I, ^{135}I), whereas six iodine isotopes have half-lives exceeding 12 hours (^{123}I, ^{124}I, ^{125}I, ^{126}I, ^{129}I, and ^{131}I).[172] The physical half-life of ^{131}I is 8 days with the emission of β-particles and γ-rays; β-particles contribute 85% of the absorbed radiation dose. ^{131}I is one of the most important radioisotopes released during nuclear accidents because of the large quantity and high volatility of ^{131}I associated with these incidents.

EXPOSURE

Four iodine isotopes (^{123}I, ^{125}I, ^{129}I, and ^{131}I) are sufficiently long-lived to potentially cause clinically important transfer from the environment to human receptors. Iodine radioisotopes (e.g., ^{129}I, ^{131}I, ^{132}I) are important fission products of nuclear reactors and nuclear weapons testing that easily volatilize into the atmosphere. Plutonium production reactors and reprocessing facilities release substantial amounts of ^{131}I into the atmosphere. The Hanford Nuclear Facility released 19.6 PBq of ^{131}I during the early years of operation between 1944 and 1956,[173] whereas the 1986 accident at Chernobyl discharged ~1,760 PBq ^{131}I over 10 days contaminating vast areas of Ukraine, Belarus, and the Russian Federation with deposition of radionuclides beyond the 30-mi exclusion zone determined by wind direction. ^{131}I and ^{137}Cs were the most important radionuclides globally, except in the immediate area around the reactor, where expelled reactor components (carbon blocks, fuel elements) determined the radiation exposure. The estimated average effective radiation dose from external radiation for the ~116,000 individuals evacuated from the area around Chernobyl was 17 mSv (range, 0.1–380 mSv).[4] In Belarus, short-lived radionuclides (e.g., ^{131}I, ^{132}I, ^{132}Te, ^{140}Ba, ^{140}La) accounted for ~60–80% of the effective external dose, whereas the contribution by the long-lived ^{137}Cs was ~3–5%. Intake of ^{131}I and other short-lived radioiodine isotopes provided the primary internal exposure during the first days and weeks after the accident, whereas the longer-lived ^{134}Cs and ^{137}Cs subsequently were the main radionuclides. Most short-lived iodine isotopes decayed before the radioactive plume reached the main contaminated areas in the Russian Federation, 150–250 km northeast of Chernobyl. Although rainfall reduced inhalation of radionuclides released from Chernobyl, intake of ^{131}I-contaminated milk and vegetables was the primary contributor to the internal thyroid dose. Table 41.19 displays the mean and collective thyroid doses in the contaminated districts surrounding Chernobyl.

Medical iodine isotopes include ^{123}I, ^{131}I, and rarely ^{125}I (hyperthyroidism, radiotherapy). Other than ^{99m}Tc, ^{131}I is the most common medical radionuclide; medical uses of ^{131}I include the diagnosis and treatment of hyperthyroidism and thyroid cancer.

DOSE

Radioiodine is the only radionuclide absorbed by the thyroid gland; the radiation dose received by the thyroid is usually greater from internal ^{131}I than external ^{131}I exposure. Incorporation of ^{131}I into thyroid hormones exposes other tissues to radiation; however, these organs receive substantially less radiation than

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 41.19. United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) estimates of the mean effective and collective thyroid dose of inhabitants in districts of the Russian Federation contaminated by the Chernobyl accident (Based on United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR)).[4]

District/Region	Population	Mean Thyroid Dose (mGy)	Collective Thyroid Dose (person-Gy)
Bryansk			
8 contaminated districts	360,000	92	33,000
Whole region	1,500,000	37	55,000
Tula			
12 contaminated districts	770,000	35	27,000
Whole region	1,900,000	26	50,000
Orel (Whole region)	1,870,000	17	15,000
Kaluga (Whole region)	1,000,000	15	15,000

TABLE 41.20. Thyroid radiation doses, effective half-lives, and radiation sources for various iodine isotopes. ^{131}I delivers the highest radiation dose, whereas ^{125}I has the longest effective half-life in the thyroid. (Adapted from Agency for Toxic Substances and Disease Registry (ATSDR)).[172]

Isotope	β-Radiation Percentage	Effective Half-Life in Thyroid (Hours)	Mean Range β-Radiation in Thyroid (mm)	Total Thyroid Dose from 1 mCi (rad)
^{123}I	77	13	0.1	76
^{125}I	73	866	0.001	3,747
^{131}I	94	177	0.4	5,627
^{132}I	90	2.3	1.7	199
^{133}I	96	20	1.3	1,355
^{135}I	90	6.7	1.1	434

the thyroid gland. The estimated average ^{131}I dose administered in developed countries for thyroid malignancies ranges from 3,500–4,760 MBq compared with 220–415 MBq for hyperthyroidism.[4] The radiation dose to the thyroid gland from absorbed radioiodine depends on the radiation emission properties of the specific isotope, including emission energy, radiation type, and effective radioactive half-life, as displayed in Table 41.20.

The dose for the treatment of Graves' disease ranges up to 30 mCi (1,110 MBq) of ^{131}I. In a study of household members of patients treated with ^{131}I (mean = 4.3 MBq; range, 2.8–5.6 MBq), 65 household members received ^{131}I radiation doses ranging from 0.01–1.09 mSv with a mean of 0.24 mSv.[174] The risk from ingesting food contaminated with radioactivity following nuclear accidents is small, except for milk contaminated with radioiodine (^{131}I). In a case series of 237 children born to mothers treated for hyperthyroidism during pregnancy, 6 offspring developed hypothyroidism; 4 of these children received 12–150 mCi (440–5,550 MBq) ^{131}I after the 12th week of gestation. Thyroid function returned to low-normal activity after 23 adults (21 women, 2 men) received fractionated doses of 1.5–3.7 MBq ^{131}I (2–8 Gy) for "unquestioned toxic diffuse or recurrent goiter."[175] Following diagnostic tests for thyroid uptake with ^{131}I resulting in doses of 0.31–0.80 Gy, hypothyroidism developed in 3 of 146 patients and 5 of 151 patients receiving 0.81–19 Gy.[176]

TOXICOKINETICS

The gastrointestinal absorption of ^{131}I is almost complete within 2 hours; ICRP models classify ^{131}I absorption as Class F (complete within 24 hours). Similarly, iodine absorption from the lungs is rapid and almost complete. Distribution occurs to the salivary glands, gastrointestinal tract, kidney, and bladder in addition to the thyroid gland; however, radioiodine concentrates in the thyroid (ICRP model: 30% absorbed dose, range 5–55%) with no other organ receiving comparable radiation doses. Fractional uptake of iodine increases in the iodine-deficient individual. The retention half-life is 80 days.[1] Recycling of inorganic iodide

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

occurs from metabolism of thyroxine and triiodothyronine released from the thyroid gland. The liver excretes ~20% of the organically bound iodine in the bile after glucuronidation of thyroxine. The amount of iodine remains relatively constant (i.e., adult mean ≈ 800 μg; range, 500–1,200 μg) primarily from renal excretion of inorganic iodine.[177] The fetal iodine concentration in the thyroid gradually increases during fetal life as thyroid follicles develop, with fetal iodine concentration 3–10-fold greater than maternal concentration near birth.[178] After the first trimester, the fetus accumulates radioiodine with potential complications of hypothyroidism and cognitive decline in offspring of mothers who received radioiodine during the second and third trimesters.[179]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The histological types of thyroid cancer are follicular, medullary, papillary, and anaplastic carcinoma (undifferentiated), with papillary carcinoma being the most common histological type of thyroid cancer in atomic bomb survivors.[180] In a study of 577 Ukrainian children exposed to ^{131}I as children during the Chernobyl incident and subsequently developing thyroid cancer, 90% of the 290 cases evaluated histopathologically were papillary carcinomas.

CLINICAL RESPONSE

The International Agency for Research on Cancer lists ^{131}I and other short-lived radioisotopes of iodine as human carcinogens (Group 1), with sufficient evidence of increased thyroid cancer in children exposed to ^{131}I-contaminated fallout from reactor accidents and nuclear weapons detonations.[1] After the 1986 Chernobyl nuclear reactor explosion in the Ukraine, an increased incidence of thyroid cancer occurred among children receiving high ^{131}I exposures in Ukraine and Belarus from contaminated milk.[181] Although the incidence of thyroid cancer in adults is not usually increased following ^{131}I exposure, studies of individuals exposed to therapeutic radioiodine during childhood also suggest an increased incidence of thyroid cancer.

Some follow-up studies of patients irradiated with ^{131}I suggest an increased cancer incidence following the medical use of thyroid isotopes;[182,183] however, most studies do not demonstrate consistent, dose-related associations between adult exposure to thyroid isotopes and increased cancer rates.[184] Potential biases for the positive studies (breast, central nervous system, kidney, digestive tract, salivary gland, bone and soft tissue sarcoma, leukemia) include detection and/or surveillance bias, shared genetic or environmental risk factors, or ^{131}I treatment. A small study suggested a marginally significant excess incidence of cancers of the bladder, kidney, digestive tract, and salivary glands.[185,186] Calculation of cancer risks in 824 thyroid cancer patients given ^{131}I demonstrated significantly elevated standardized incidence rates (SIRs) for tumors of the salivary glands, genital organs, kidney, and adrenal gland; however, the lack of a detectable increase in the SIR over time did not support a causal relationship.[187] The SIR of leukemia for 46,988 Swedish patients irradiated with a mean bone marrow dose of 14 mGy ^{131}I was 1.09 (95% CI: 0.94–1.25); the study had sufficient power to detect a 25% increase in the relative risk.[188] A follow-up study of patients treated with ^{131}I for thyrotoxicosis did not detect an increased leukemia incidence; however, the average follow-up period (6.5 years) is relatively short for the development of leukemia in older patients.[189] A retrospective cohort study of patients receiving ^{131}I for diagnostic purposes did not demonstrate an elevated incidence of thyroid cancer.[190] Studies of patients receiving diagnostic or therapeutic ^{131}I typically contain primarily adults with less radiosensitivity to thyroid cancer than children.

HEALTH SURVEILLANCE

Risk Assessment

The childhood thyroid gland, red bone marrow, and premenopausal female breast are the most radiosensitive organs in the body. Based on a pooled analysis of atomic bomb survivors and children receiving radiotherapy (enlarged thymus glands, tonsils, *Tinea capitis*), the highest risk for thyroid cancer occurs 15–29 years after exposure of children <10 years of age to thyroid doses of >1 Gy with evidence of a threshold for increasing cancer risk in this age group at a thyroid dose of 0.1 Gy.[191] Currently, there is no direct evidence indicating that exposure to the medical use of ^{131}I induces thyroid cancers in humans.[1] This lack of data correlating ^{131}I treatment of adults with thyroid cancer is consistent with the studies of atomic bomb survivors that demonstrated no increased risk of thyroid cancer when exposure occurred after the age of 20 years.[192] The ^{131}I doses to organs including the red bone marrow, gastrointestinal tract, breast, and urinary tract during medical use are typically below the level associated with an increased incidence of cancer in patients exposed during adulthood.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Environmental Monitoring

The maximum permissible thyroid dose for continuous exposure to ^{131}I is 15 rem/year. Emergency reference levels are 0.25 μCi/L as a peak level in milk and 1.5 μCi/m^2 on pasture. Exceeding these reference levels requires the diversion of contaminated milk from direct use to milk products (e.g., cheese, condensed milk) and changing the cow's forage. The US Nuclear Regulatory Commission allows the release of outpatients treated with ^{131}I when the total effective dose equivalent to any individual near the patient is <5.0 mSv.

TREATMENT

Clinically significant ^{131}I exposures typically occur after nuclear reactor incidents (e.g., Chernobyl and Fukushima) rather than nuclear bomb detonations because of the limitation of exposure from the latter by atmosphere dilution. Potassium iodide is a relatively nontoxic, USFDA-approved blocking agent that prevents ^{131}I incorporation when administered before or shortly following exposure; this agent should be given within 3–4 hours of the release of radioiodine to prevent radioiodine uptake by the thyroid gland. Blocking therapy is most effective when given before radioiodine exposure to saturate the thyroid with nonradioactive iodine; the efficacy markedly diminishes by 12 hours postexposure. Potassium iodide (KI) is available in 130 mg tablets; the shelf-life of these tablets is 5 years. The US FDA recommended dosage of KI following radioiodine exposure is listed in Table 41.21. The administration of KI should continue until the risk of exposure ceases or until other measures (evacuation, control of food sources, sheltering) eliminate the risk of radioiodine exposure. Individuals should be monitored for the development of hypothyroidism up to 2 years postexposure.[193] Potassium iodide does not prevent the uptake of ^{131}I in organs other than the thyroid or mitigate the injury of any organs to other radionuclides.

For patients receiving thyroid doses over 100 rads, thyroid function tests including the TSH level should be evaluated within 2–3 months; then, they should be followed every 6–12 months for several years.[24] Chelation with DTPA is ineffective. The role of vitamin C as a radioprotector for exposure to ^{131}I via its antioxidant properties has been suggested by animal studies;[194] however, the efficacy of vitamin C to reduce hypothyroidism or cancer is unproven.[195]

TABLE 41.21. United States Food and Drug Administration (USFDA) recommendations for potassium iodine following excessive radioiodine exposure.

Category	Age	KI Dose[a]
Adults including lactating women, adolescents over 150 lb	>18 years	130 mg
Older children and adolescents under 150 lb	3–18 years	65 mg
Young children	1 month to 3 years	32 mg
Neonates	<1 month	16 mg

[a] Potassium iodide, usually available in 130 mg tablets.

MERCURY

All but two of the five isotopes of mercury have physical half-lives of less than 1 day. The exceptions are ^{197}Hg and ^{203}Hg, which possess physical half-lives of 65 hours and 47 days, respectively. The decay of ^{197}Hg produces two X-rays, whereas the decay of ^{203}Hg emits β-particles and X-rays. Radionuclides of mercury are present in biomedical research labs and some industrial settings related to mercury isotope production. The effective half-life of ^{203}Hg in two workers inhaling this radioisotope was 16–17 days. The short half-lives of these isotopes limit the adverse effects of internal contamination. DMSA, penicillamine, and dimercaprol are chelating agents with potential usefulness; however, human data are inadequate to guide therapy.

PHOSPHORUS

^{32}P was the first radioisotope produced for biological research resulting in the introduction of $^{32}PO_4$ as a treatment for polycythemia vera in 1939.[196] Polycythemia vera is a clonal malignancy of the pluripotent hematological stem cells with an increased risk of developing leukemia.

PHYSIOCHEMICAL PROPERTIES

Phosphorus is a common, naturally occurring, reactive nonmetal that does not exist in the environment in its elemental form; ^{31}P is the natural, nonradioactive isotope, whereas ^{32}P is a synthesized radionuclide. The physical half-life of ^{32}P is 14.2 days with the emission of β-particles to decay back to ^{32}S; ^{32}P has low specific activity of 185–300 MBq (5–8 mCi). The effective half-life of ^{32}P is also 14 days. The effective mean energy of these β-particles (i.e., 0.69 MeV) corresponds to a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

maximum range in tissue of 7 mm.[25] ^{32}P does not emit photons.

EXPOSURE

The primary medical use for ^{32}P is the treatment of polycythemia vera. This isotope is also a radioactive tracer used to identify tumors prior to removal. Historical medical uses include the treatment of chronic myelocytic and lymphocytic leukemias.

DOSE

Individual treatments for polycythemia vera typically involve the use of 150–170 MBq $^{32}PO_4$. Estimates of the average skeletal dose of 300 rad/7.4×10^8 Bq are 4 nGy/Bq based on administered activities of $1.85–2.96 \times 10^8$ Bq.[1] Human exposures include intentional ingestions and inappropriate administration of four times (16.2 mCi) the prescribed dose; the latter patient developed progressive decline in red and white blood cell counts.[197] The patient remained asymptomatic during the recovery period. The ingestion of ~600 μCi resulted in a total effective dose equivalent of 48 mSv.[198] The patient remained asymptomatic.

TOXICOKINETICS

Dietary phosphorus and inorganic phosphorus compounds are generally well absorbed from the gastrointestinal tract;[199] however, the half-lives of some relatively insoluble phosphates (e.g., bismuth, iron, magnesium, tin, zinc) in the lungs after inhalation are 3 months.[1] For soluble ^{32}P compounds, the critical organ is the bone resulting in the accumulation of ~20–30% of the absorbed dose. ^{32}P distributes throughout the body; however, distribution to the skeleton exceeds soft tissue by 4–10-fold. Following intravenous injection of ^{32}P, the biological half-life of ^{32}P in the body was 39 days as measured by whole-body counting.[200] Dietary balance studies suggest that the retention half-time of phosphorus in bones is ~4 years resulting in radiation exposure primarily on bone surfaces. The kidneys excrete 5–10% of the absorbed dose within 1 day and up to 50% within 1 week.[201] Fecal elimination is low (i.e., <2%). Rodent studies suggest phosphorus easily crosses the placenta.[1]

CLINICAL RESPONSE

The IARC classifies ^{32}P as a human carcinogen (Group 1) with sufficient evidence that therapeutic ingestion or injection of ^{32}P administered as inorganic phosphate causes acute leukemia; observational follow-up studies of a series of patients with polycythemia vera treated with $^{32}PO_4$ demonstrate a clear increased incidence of acute leukemia.[1] A study of 1,222 patients treated with ^{32}P for polycythemia vera demonstrated an increased incidence of acute leukemia; however, the association of myeloproliferative disease with leukemia complicates the interpretation of the causal association between exposure to ^{32}P and an elevated risk of leukemia.[202] The study did not detect a significant difference in the incidence of nonhematological cancers. After 10–18 years of follow-up in the Polycythemia Vera Study Group trial, 2 cases of acute leukemia developed in 134 patients treated by phlebotomy (control), compared with 16 cases of acute leukemia among 156 patients treated with ^{32}P and 19 cases of acute leukemia plus 5 cases of large-cell lymphocytic lymphoma in 141 patients treated with chlorambucil.[203] Survival was comparable in the treatment and control groups because of the increased incidence of thrombosis in controls.

TREATMENT

Aluminum hydroxide antacids (600 mg tablet t.i.d. or 320 mg/5 mL t.i.d.) may reduce gastrointestinal absorption by acting as a phosphate binder; phosphate compounds act as a diluting agent. Typical treatment for internal contamination from phosphorus involves hydration plus a phosphate binder (e.g., adult dose: dibasic potassium phosphate 250 mg tabs, 1–2 tabs qid with a glass of water at meals and bedtime) listed under binders above; however, there are few data to determine the effectiveness of these agents.

NEPTUNIUM

PHYSIOCHEMICAL PROPERTIES

The physical half-lives of neptunium isotopes are highly variable ranging from <1 hour for neptunium isotopes with masses of <233 to 2,100,000 years for ^{237}Np. The half-life of ^{239}Np is 2.35 days. The form of neptunium in nature is primarily pentavalent NpO_2^+ ions; these compounds are less susceptible to hydrolysis than other actinide ions.

EXPOSURE

Neptunium exists in the environment as the long-lived, α-emitting ^{237}Np; this isotope exists in minute amounts.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The principal sources of neptunium are: 1) fallout from nuclear explosions; 2) ^{237}Np in nuclear waste; 3) industrial processing of ^{237}Np produced in fission reactors; and 4) effluent from fission reactors.[204] Although the amount of ^{237}Np in high-level nuclear waste is small, the long half-life of ^{237}Np results in ^{237}Np being the most hazardous isotope in the waste over a period of 10,000–30,000,000 years after release.[205] Nuclear reactors using enriched uranium produce ^{237}Np levels that are somewhat >0.1% of the plutonium generated. The β-emitting isotope ^{239}Np may produce up to 75% of the β-radiation in the first 4 days following a nuclear explosion.[204] Within 48 hours of the nuclear test at Enewetak, the short-lived isotope ^{239}Np was the most prominent radionuclide in marine plankton.[206]

ENVIRONMENTAL FATE

Neptunium is more mobile and environmentally available than other transuranic elements; however, the medical significance of neptunium isotopes is limited by their short half-lives, lack of persistence in the environment (^{239}Np), and small quantity (^{237}Np). Consequently, radiation exposure from these isotopes is minimal.

TOXICOKINETICS

The mean value for the gastrointestinal absorption of ingested neptunium in a study of human volunteers was 0.02% with a range of 0.0095–0.03% consistent with animal studies suggesting GI absorption in the range of 0.1%;[161,207] however, the IRCP uses a f_1 value of 1% (i.e., medium absorption). The ICRP assigns all neptunium compounds to the inhalation class W (weeks) that includes all other actinides except the insoluble oxides and hydroxides of thorium, uranium, and plutonium. Animal studies indicate bone is the primary neptunium deposition site with most of the remaining neptunium being distributed to the liver. Early neptunium excretion probably is somewhat higher (25% reaching the blood) than plutonium (10%). The ICRP assumes 60% of the neptunium in the blood will deposit on the surface of the bone, whereas 15% of neptunium in the circulation accumulates in the liver with retention half-times of >20 years and 2–3 years, respectively. Primate studies suggest the placental transfer of ^{237}Np citrate is limited with fetal retention of ~1–2%.[208]

CLINICAL RESPONSE

Although ^{239}Np probably contributes significantly to the production of β-burns in the victims of nuclear explosions during the early phase of nuclear fallout, neptunium is not associated with other human health effects.[204] The short ^{239}Np half-life limits radiation damage to the gastrointestinal mucosa and lungs. Because of the low-specific radioactivity of ^{237}Np, chemical toxicity of ^{237}Np may contribute to the effects in animal experiments more than radiation-induced damage. The International Agency for Research on Cancer (IARC) considers ^{237}Np an animal carcinogen with sufficient evidence of carcinogenicity in animal experiments (i.e., osteosarcomas in female rats following injection of ^{237}Np nitrate,[209] squamous cell cancer, and adenocarcinomas of the lung after inhaling $^{237}NpO_2$) with little human data.[1]

TREATMENT

Because the ^{237}Np-DTPA complex is unstable *in vivo*, chelation with DTPA following exposure is ineffective.[210] Neptunium is more tightly bound to bone than plutonium; consequently, DTPA significantly removes neptunium from soft tissue stores rather than bone.[211] Animal studies suggest the combination of iron chelators (e.g., desferrioxamine or carboxylated catechoylamide 3,4,3-LICAM-C, DTPA) may be more effective than DTPA alone.[212]

PLUTONIUM

PHYSICOCHEMICAL PROPERTIES

Plutonium is primarily an artificial element formed as a by-product of uranium production; the neutron capture and β-decay of ^{238}U produce plutonium. The principal plutonium isotopes (^{238}Pu, ^{239}Pu) are produced for fuel in nuclear power reactors and components of nuclear weapons. ^{239}Pu typically refers to the combination of α-emitters, ^{239}Pu, and lesser amounts of ^{240}Pu. All plutonium contains some ^{241}Am (half-life, 432.2 years) that contributes to the overall radiation dose.

There are 15 known Pu isotopes with atomic weights ranging from 232–246. The most biologically important isotopes range from 236–243; Table 41.22 displays some physical properties of this series. These isotopes emit primarily α-particles during decay, except for the β-particles produced by ^{241}Pu. The radioactive half-lives and biological retention times of the two most common plutonium isotopes (^{238}Pu and ^{239}Pu) are very long; therefore, incorporation of these isotopes results in prolonged exposure to α-radiation.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 41.22. Physical properties of plutonium isotopes.

Physical Property	^{236}Pu	^{237}Pu	^{238}Pu	^{239}Pu	^{240}Pu	^{241}Pu	^{242}Pu	^{243}Pu
Radioactivity half-life (years)	2.85	0.125	87.8	2.439×10^{4}	6.537×10^{3}	15.02	3.87×10^{5}	5.66×10^{-4}
Principal decay mode	α-particles	Electron capture	α-particle, X-rays	α-particle, X-rays	α-particle	β-particle	α-particle	β-particle
Mean α-energy (MeV)	5.75	—	5.46	5.15	5.15		4.89	
Specific activity (μCi/g)	5.32×10^{8}	1.21×10^{10}	1.71×10^{7}	6.13×10^{4}	2.28×10^{5}	9.90×10^{7}	3.82×10^{3}	2.60×10^{12}
Mass/μCi (g)	1.88×10^{-9}	8.28×10^{-11}	5.84×10^{-8}	1.63×10^{-5}	4.38×10^{-6}	1.01×10^{-8}	2.62×10^{-4}	3.84×10^{-13}
Relative mass[a]	1.15×10^{-4}	5.08×10^{-6}	3.58×10^{-3}	1.00	26.9	6.19×10^{4}	16.1	2.36×10^{8}

[a] Mass relative to 1 μCi of ^{239}Pu set as 1.

During decay, ^{239}Pu also emits low-energy X-rays capable of penetrating several cm of tissue; these X-rays allow detection of this isotope in the lung and wounds. Although plutonium has four valence states (3^{+}–6^{+}), almost all plutonium in biological systems appears in the IV valence. Hydrolysis of Pu (4^{+}) produces relatively insoluble polymers that degrade slowly in the body. Pu (3^{+}) and Pu (6^{+}) are more soluble than Pu (IV); therefore, the former two compounds are more easily absorbed and excreted. ^{238}Pu and some ^{239}Pu compounds (e.g., nitrates, citrates) are more soluble and easily absorbed into the circulation than ^{239}Pu oxides. However, the solubility of ^{239}Pu oxides following inhalation depends partly on formation of the aerosol with high-fired (1,000°C), completely oxidized $^{239}PuO_2$ being sparingly soluble, whereas materials formed at lower temperatures, less complete oxidation, and mixed with other metals (e.g., calcium, magnesium, potassium, sodium) are more soluble.

EXPOSURE

Thermoelectric generation systems in spacecraft, cardiac pacemakers, and other power sources use ^{238}Pu, whereas nuclear fission in nuclear reactors accounts for most of the production of ^{239}Pu and ^{240}Pu.[213] The plutonium from reactors exists primarily in the form of oxides. Plutonium dioxides formed at temperatures >700°C have much lower solubility than the oxides created by air oxidation.[214] Uranium and plutonium oxides are inhalable components of mixed oxide fuels at nuclear facilities with potential occupational exposure to inhaled radiation and increased lung cancer risk.[215,216] The United States detonated a nuclear device at the Bikini Atoll on March 1, 1954, that unexpectedly released a large amount of radioactive fallout. Based on 1991 fission tract analysis data over 40 years, mean effective dose equivalent from ^{239}Pu was 0.62 mSv for Rongelap inhabitants and 1.6 mSv for Utirik inhabitants.[217] In a 1991 study of 69 urine samples from inhabitants of Enewetak Atoll, the committed effective doses of plutonium were 0.2 mSv.[218]

TOXICOKINETICS

Absorption

Plutonium does not exist as a simple ion at physiological pH. Hydrolysis of plutonium in the gastrointestinal tract and formation of relatively insoluble polymers minimize plutonium absorption after ingestion, depending on age, nutritional factors, stomach contents, and relative solubility of the compounds.[219] Animal studies suggest gastrointestinal absorption increases with nitrate or citrate solutions (0.003–0.01%),[220] very acidic solutions, neonates (3–6%),[221] an empty stomach (0.1–0.15%),[222] and iron deficiency (4-fold increase).[223] An α-spectrometry analysis of urinary ^{238}Pu and ^{239}Pu specific activity from bioassay examinations of 1,013 Mayak workers suggested the solubility of ^{238}Pu was associated with the relative amounts of ^{238}Pu/^{239}Pu in the particles and calcination temperatures during the preparation of the dioxides.[224]

Plutonium absorption from the lungs depends on the chemical compound (i.e., solubility), valence, particle size, and the mass deposited. The insoluble forms of plutonium (oxides) remain in the reticuloendothelial system after phagocytosis by macrophages and alveolar cells for an extended time. Dermal Pu absorption from intact skin is insignificant.[219] The absorption rate of ^{239}Pu nitrate in a 0.4 N nitric acid solution through the intact palmar skin of a human volunteer was 0.0002%/hour.[225]

Distribution

Animal studies indicate the plasma protein, transferrin, binds ~90% of the absorbed dose with most incorporated Pu distributed to the skeleton and liver.[226]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

A study of former nuclear industry workers demonstrated absorbed Pu distributes primarily to bones (~50%, primarily red marrow in trabecular bone rather than yellow marrow in cortical bone) followed by the liver (~30%) and smaller amounts in striated muscle.[227,228] In contrast to the uniform distribution of radium in bones, most plutonium (i.e., 93–97%) lies on the surface of the bone rather than in the marrow.[229,230] Because ^{239}Pu dioxide is poorly soluble, the lungs and surrounding lymph nodes retain most deposited burden of ^{239}Pu;[219] however, ^{238}Pu dioxide is solubilized and transported to the skeleton and liver.[231] In postmortem studies of 85 former Mayak nuclear workers exposed to Pu aerosols, ^{238}Pu accumulation fraction in the bodies of these workers ranged from 0.13–27.5%.[232] Although early animal studies suggested systemic translocation, particularly to the skeleton, was more rapid for ^{238}Pu than ^{239}Pu, the deposition of these radionuclides in the main organs was statistically similar in this study.

Elimination

A 30-year follow-up study of workers exposed to plutonium indicates the kidney excretes more plutonium than the intestines.[233] The kidney eliminates plutonium slowly from the blood at a rate of 3–4% of plasma plutonium/day.[234] The precision of models estimating total body burden based on the urinary Pu excretion rate depends on knowledge concerning particle size, chemical properties of the specific form of plutonium, and the urinary excretion rate of the individual.[235] Based on postmortem tissue analysis, the Langham power function model as modified by Leggett and Eckerman and the two-compartment exponential model proposed by the IRCP accurately predict elimination rates within a factor of 2.[236] Plutonium retention time in bone is very long with a retention $t_{1/2}$ = 100–200 years. Over 50–90% of inhaled ^{239}Pu dioxide remains in the lung for years. In 1985, a puncture wound in the right index finger of a Hanford worker resulted in the initial deposition of 48 kBq of transuranic α-activity, primarily ^{239}Pu, ^{240}Pu, and ^{241}Am.[237] Urinary Pu excretion after cessation of chelation therapy remained relatively constant over ~22½ years at 10–20 mBq/day.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In animals exposed via inhalation to ^{238}Pu (3.7×10^4 Bq/kg) or ^{239}Pu dioxide (3.7×10^3 Bq/kg), radiation pneumonitis develops, characterized by fibrosis, alveolar edema, and occasionally by pulmonary hyperplasia and metaplasia.[219] At all Pu doses below levels producing radiation pneumonitis, interstitial fibrosis developed from chronic pulmonary irradiation by α-particles. Depending on the animal species, chemical form, and exposure route, plutonium causes lung cancer (bronchiolar-alveolar carcinomas), liver cancers (bile duct adenomas, bile duct carcinomas, sarcomas, and rarely hepatic cell tumors), and bone tumors (primarily osteogenic sarcomas in trabecular bone). Lung tumors occur only after inhalation, but more soluble plutonium also causes liver and bone tumors in animals following inhalation. Animal studies indicating uncomplicated pulmonary emphysema does not increase lung sensitivity to carcinogenic effects of inhaled ^{239}Pu dioxide.[238]

CLINICAL RESPONSE

Lungs

Case studies of early Mayak plutonium workers in the Soviet Union reported fatal acute/chronic radiation sickness, radiation pneumonitis, and pulmonary fibrosis, primarily from exposure to ^{239}Pu.[239] In a retrospective study of 326 plutonium-exposed workers with absorbed lung doses ranging from 0–28 Sv and 194 unexposed workers, scores on interstitial abnormalities evaluated by the International Labor Organization profusion scoring system were significantly higher in the exposed group (17.5%) than the unexposed group (7.2%, $P < 0.01$) after controlling for smoking, asbestos exposure, and age, particularly for workers receiving >10 Sv.[240] The risk of pulmonary fibrosis changes was 5.3-fold higher (95% CI: 1.2–23.4) in the latter group. Animal studies using ^{238}Pu and ^{239}Pu oxides suggest the development of pulmonary fibrosis depends on cumulative dose and isotope type.[241]

Skin

Fibrous nodules appear near sites of Pu deposition within a few months to years.[242] Atrophy and dyskeratosis from α-radiation extend into basal area of the epidermis. The similarity of these epidermal lesions to precancerous skin changes suggests the possibility that cancer may develop in these lesions.[243]

Carcinogenesis

Most studies of plutonium workers in the United Kingdom and the USA did not detect elevated risks of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cancer, primarily because of the relatively low radiation exposures with few workers accumulating plutonium body burdens exceeding 1 kBq; however, an increased incidence of lung, bone, and liver cancer occurred in Russian cohorts working at the Mayak nuclear complex in the southern Urals exposed to higher radiation doses.[1] The latter studies demonstrate statistically significant cancer risks following the accumulation of body burdens of >3 kBq with equivalent lung doses of >80 Sv assuming a RBE of 20. These three cancer sites represent the organs accumulating the highest doses of incorporated plutonium.

Although several epidemiological studies of US plutonium workers have not demonstrated a definite causal association between plutonium exposure and cancer, the IARC classifies ^{239}Pu as a Group 1 (human) carcinogen based on cancer in heavily exposed Russian Pu workers (i.e., body burden >3 kBq) to ^{239}Pu at the Mayak plutonium production plant in the Russian Federation. Generally, the cancer mortality rates were not elevated in Pu workers with estimated body burdens of 1 kBq.[244,245] Using 5-year cancer induction rates, a statistically significant elevation of the all-cause mortality rate occurred in a mortality study of 5,413 white males with at least 2 years of employment at a plutonium weapons facility; however, this elevation did not demonstrate a linear dose-response.[246] A case study of 26 Manhattan project workers reported a Pu-exposed worker with osteosarcoma of the coccyx;[247] four blood cell neoplasms (multiple myeloma, myeloid leukemia, non-Hodgkin's lymphoma, reticulum cell sarcoma) occurred in workers at Rocky Flats.[246] US plutonium workers have been examined periodically over the past 50 years to identify possible health effects from internal plutonium depositions. The effective doses for 26 white male workers employed in original plutonium research and development work at Los Alamos ranged from 0.1–7.2 Sv with a median value of 1.25 Sv.[248] Compared with 876 unexposed Los Alamos workers, the SMR for the 26 workers was not statistically elevated (SMR = 0.77; n = 8 deaths) after 50 years of follow-up; 3 of these deaths involved cancer (prostate, lung, bone).

HEALTH SURVEILLANCE

Although default values for absorption parameters in the ICRP model provide reasonable approximations of Pu absorption following inhalation,[249] accurate determination of the risk from occupational Pu exposure depends on reliable assumptions regarding the chemical form of inhaled plutonium, Pu distribution in the lungs, and absorption values for diffusion from the lungs to blood.[250] A Russian study examined the incidences of lung, liver, bone, and associated connective tissue cancers in 16,679 male and 5,687 female workers at the reactors, radiochemical manufacturing, and plutonium production facilities of the Mayak nuclear complex from 1948–1982 with follow-up through 2004.[251] Radiation exposure involved internally incorporated Pu and external γ-radiation. The study demonstrated a significant internal plutonium dose-response for evaluated lung cancer subtypes (i.e., adenocarcinoma, squamous cell, other epithelial) in *men*; the estimated excess relative risk (ERR/Gy for adenocarcinoma was 32.5; 95% CI: 16.3–71.9) compared with squamous cell lung cancer (EER/Gy = 3.1; 95% CI: 0.3–9.1). A linear-quadratic function described the dose-response for liver cancer, particularly above 2 Gy, whereas the trend for bone cancer and plutonium was nonsignificant. Analysis of smoking and lung cancer risk indicates smoking is sub-multiplicative and super-additive.[216] A study of 319 deceased US nuclear workers employed between 1943 and 1995 with histories of transuranic radionuclides intake did not demonstrate an elevated risk of overall cancer mortality; however, the risk of death from any type of cancer increased with a history of smoking (OR = 5.41; 95% CI: 1.42–20.67) and cigarette smoking rate in packs/day (OR = 2.70; 95% CI: 1.37–5.30).[252] Based on excess relative risk estimates/unit absorbed lung dose from α-radiation in plutonium workers at the Mayak nuclear facility, the relative biological effectiveness (RBE) of inhaled ^{239}Pu ranges from 10–20, with the upper limit providing a sufficient radiation weighting factor for α-particles during occupational exposures.[253]

TREATMENT

Wounds

Animal experiments indicate plutonium absorption into the systemic circulation after wound contamination is relatively slow.[254] Measurement of the amount of 17 keV X-rays emitted with the α-particles is an accurate measure of wound contamination. Treatment of skin wounds contaminated with plutonium includes decontamination, excision of the contaminated portion of the wound, and early and frequent chelation with intravenous or inhaled DTPA.[255] Solutions available to remove plutonium firmly fixed to skin include liquid soap and detergent, 4% $KMnO_4$, and 5% $NaHSO_3$. Preferably, chelation therapy should begin within several hours of the confirmation of incorporated Pu doses

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

exceeding currently recommended standards. Ca-DTPA is the chelator of choice during the first 24 hours after internal contamination, whereas both DTPA preparations are probably equally effective after the initial 24 hours postexposure.[256]

Inhalation

Ca-DTPA and Zn-DTPA are effective agents for reducing the amount of plutonium in the liver and bones following systemic absorption of soluble Pu forms, particularly when administered immediately after contamination;[257] however, during the first 24 hours after internal contamination, Ca-DTPA probably enhances urinary Pu excretion more than Zn-DTPA or $CaNa_2EDTA$.[258] In animals, these chelating agents decrease the incidence of osteosarcomas after the intravenous injection of ^{239}Pu.[259] These agents are available through the Medical and Health Sciences Division of Oak Ridge Associated Universities in Oak Ridge, Tennessee (https://www.orau.gov/hsc/RadMassCasualties/assets/6_Pharmacotherapy_Handout.pdf).

After obtaining baseline blood (CBC with differential, BUN, serum creatinine) and urine samples (urinalysis and urine radioassay), 1 g Ca-DTPA is administered to adults unless Zn-DTPA is indicated for pregnant women. This dose can be diluted in 100–250 mL D5W or normal saline and administered over 1 hour. Twenty-four-hour urine and fecal samples are collected for bioassay; whole-body and chest counting are initiated to estimate the amount of contamination and efficacy of chelation. Repeat doses of 1 g CaDTPA or 1 g Zn-DTPA may be administered daily up to 5 days/week as determined by the radioassay data and exposure history. Most patients receive a single DTPA dose. Supplemental zinc therapy (220 mg zinc sulfate daily) may be necessary during long-term Ca-DTPA chelation. Ca-DTPA treatment is contraindicated in the presence of preexisting serious kidney disease or depressed myelopoietic function (e.g., leukopenia or thrombocytopenia).

The use of an aerosol of Ca-DTPA is an alternative treatment for decreasing the burden of soluble plutonium forms (^{238}Pu and ^{239}Pu nitrate or tributylphosphate) in the lungs;[83] however, there is no clear evidence that inhalation is superior to IV treatment because of the limited amount of DTPA particles reaching alveolar tissues, unless DTPA administration via inhalation is a more rapid option. Lung monitoring may be useful for the ^{238}Pu and ^{239}Pu isotopes; however, ^{241}Pu emits only nonpenetrating radiation. Suggested guidelines for initiating DTPA treatment for soluble ^{238}Pu and ^{239}Pu exposures include consideration for estimated internal doses of 20–200 mSv and implementation of treatment at doses exceeding 200 mSv.[93] Zn-DTPA is a less desirable form for aerosol administration because of its metallic taste. The removal of insoluble Pu forms is much more difficult, especially after radionuclide uptake by macrophages. Bronchopulmonary lavage is the only effective treatment for the deposition of ^{239}Pu oxides in the lungs; however, the amount (~20%) of plutonium removed from the lungs with this procedure is limited.

POLONIUM

HISTORY

Marie Curie discovered ^{210}Po when she separated this radionuclide from pitchblende in 1898;[260] in 1910, she and André-Louis Debierne isolated 0.1 mg polonium by the spark spectrum technique. She received the Nobel Prize in 1911 for the discovery of polonium and radium. The assassination of the former lieutenant colonel of the Russian Federal Security Service and Russian writer-dissident, Alexander Litvinenko, in London on November 23, 2006, focused media attention on radiation-induced toxicity from the internal polonium-210 (^{210}Po) contamination.[261] He became ill on November 1, 2006, after ingesting tea contaminated with a soluble polonium salt; autoradiography of hair samples demonstrated two regions of ^{210}Po activity suggesting an earlier poisoning attempt during October 2006 involving one-hundredth the estimated dose for November 1, 2006, with resulting renal radiation dose approaching 3 Gy from the first poisoning compared with organ doses ranging from 20 to over 100 Gy from the second poisoning.[262] British experts estimated he ingested ~0.2–8.5 μg ^{210}Po (27–1,408 MBq) from the tainted tea, assuming ^{210}Po was the only ingested radionuclide.[263] He died 23 days after drinking the tainted tea with the postmortem examination demonstrating ^{210}Po concentrations ~10^9 times normal background levels.[264]

During his medical care, hospital personnel surveyed Mr. Litvinenko with a standard Geiger–Mueller counter without detecting radioactivity; however, ^{210}Po decays primarily by the release of α-particles undetectable at the surface of the skin by a Geiger–Mueller counter following internal contamination.[265] Subsequent investigations detected widespread radioactive contamination at various local and more distant hotels, offices, and hospitals.[266] Testing involved over 700 UK residents

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with 139 individuals demonstrating evidence of internal contamination with ^{210}Po as defined by urinary ^{210}Po excretion of >30 mBq/24 hours; however, the risk of adverse effects from this contamination was not considered clinically significant with the radiation dose in only a few individuals exceeding 1 mSv.[267] The 43 healthcare providers were unaware of his radioactive contamination during his 3-week illness; these providers used standard precautions without developing significant internal contamination.

PHYSIOCHEMICAL PROPERTIES

Polonium is the first element in the periodic table with all isotopes being radioactive; there are 33 isotopes ranging in mass from 188–220; however, only isotopes 208, 209, and 210 have half-lives exceeding 1 day.[268] The most widely available Po isotope is ^{210}Polonium, a silvery-gray, soft, volatile, naturally occurring radioactive element that is part of the uranium (^{238}U) decay series. Along with ^{210}Pb, ^{210}Po is a relatively long-lived decay product of ^{222}radon. Polonium has several oxidation states (−2, 2, 4, 6), with Po^{4+} being the most stable in aqueous solutions.

^{210}Po is not a gas; therefore, release of this isotope to the air involves particulates rather than vapors. Po belongs to Group 16 (Group VIA) of the periodic table along with oxygen, sulfur, and selenium; however, the amino acids, methionine and selenomethionine do not readily incorporate Po. This radionuclide decays to ^{206}Po by α-decay accompanied by 1/100,000 decays with γ-emission, as displayed in Equation 41.4. ^{210}Po emits a pure α-particle with a relatively high kinetic energy of 5.3 MeV. The range of these α-particles in tissue is low (i.e., 40–50 μm). This radionuclide decays with a physical half-life of ~138 days and an effective biological half-life of 46 days.[1]

$$^{210}_{84}\text{Po} \rightarrow {}^{206}_{82}\text{Pb} + {}^{4}_{2}\text{He} \qquad \text{(Equation 41.4)}$$

Polonium easily forms simple, water-soluble salts (e.g., chlorides) in dilute acid solutions; this radionuclide has a high affinity for proteins. The specific activity of ^{210}Po (1.66×10^{14} Bq/g) is relatively high; 10 μg Po chloride salt is equivalent to 1 GBq.[261] One μg Po emits as many α-particles as 5 mg ^{226}Ra and 446 kg ^{238}U.[268] The linear transfer energy of ^{210}Po in water is 100 keV/μm, sufficient to penetrate ~50 μm in tissue including human cells (typically, 10–30 μm in diameter).

EXPOSURE

Production Processes

^{210}Po is a ubiquitous, naturally occurring radionuclide formed from the uranium-238 decay chain (i.e., decay of ^{210}Pb by release of ^{222}Rn), as displayed in Figure 41.2.

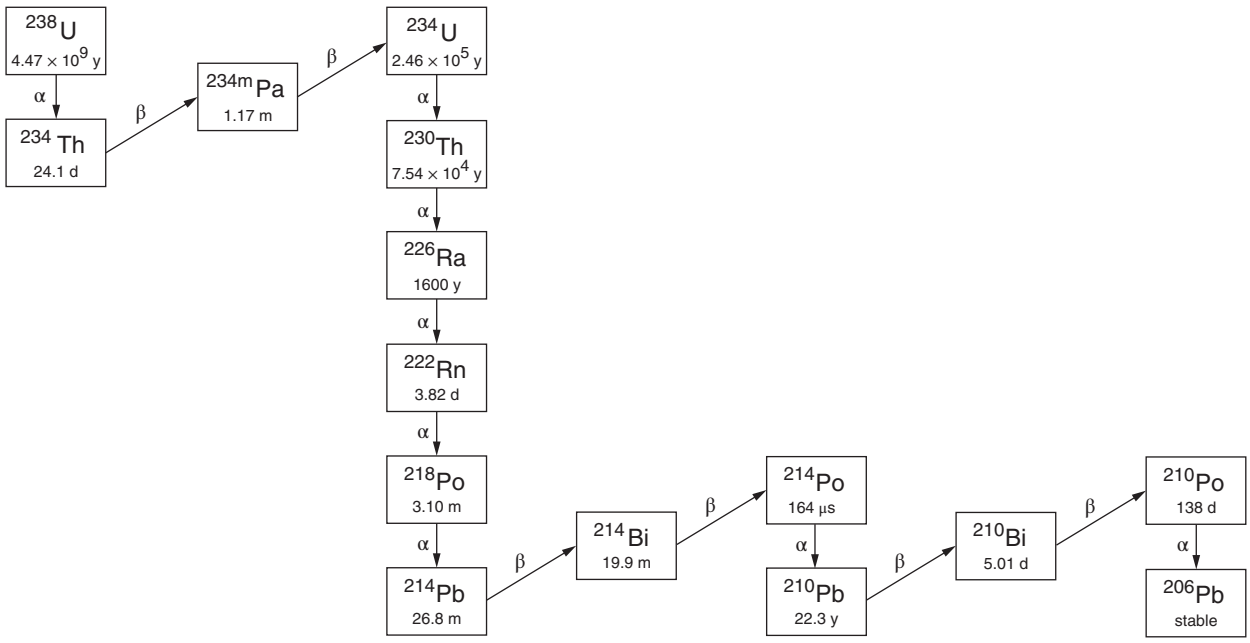

FIGURE 41.2. The ^{238}uranium (^{238}U) decay series including the formation of ^{210}polonium (^{210}Po). (Redrawn from Matthews et al.).[260]

Neutron irradiation of ^{209}bismuth in a nuclear reactor is the main commercial process for ^{210}Po production; ^{210}bismuth decays to ^{210}Po through β-decay with a half-life of 5 days.[268] ^{210}Po is a natural soft metal with several industrial applications including static eliminator in combination with gold foil (paper rolling, spinning synthetic fibers), a lightweight heat source for thermoelectric power, and a neutron source with beryllium for early atomic weapons.

Sources

Environment

Environmental concentrations of ^{210}Po are relatively very low.[269] In aqueous environments, Po occurs primarily as a slightly soluble tetravalent compound that forms colloids and easily adheres to particulates.[268] Polonium tends to volatilize at temperatures near 50°C; alkyl derivatives of Po and the reduced form (H_2Po) are volatile. Potential sources of ^{210}Po in the atmosphere and surface waters include the deposition of ^{210}Po from the decay and volatilization of ^{226}Ra and ^{222}Rn from the ground, volcanic eruptions, fires, resuspension of soil dust, migration of sea salt, zircon processing, cement production, phosphate processing, and burning of fossil fuel.[270] ^{210}Po (and ^{210}Pb) are the final long-lived radionuclides in the decay of ^{238}U in the earth's crust. The estimated population radiation dose of ^{210}Po in surface air is ~50 μBq/m^3.[271] The typical activity concentration of ^{210}Po is 7–50 mBq/L in private wells, 1–100 mBq/L in rainwater, and 1–5 mBq/L in ocean water.[268] A study of groundwater wells in California demonstrated ^{210}Po activity in water samples ranging from 0.25–555 mBq/L with mean and median activities of 57.8 mBq/L and 3.33 mBq/L, respectively.[272] In soils, ^{210}Po associates with organic matter and adsorbs to minerals, particularly clays. The activity concentration depends on soil type, depth, and atmospheric precipitation with average activity concentrations of 20–240 Bq/kg. Contaminated soils (e.g., uranium mining residues) may contain 15,000–22,000 Bq/kg ^{210}Po.[273]

Food

The chemical form of ^{210}Po in foods is not well defined; differences in bioavailability probably account for some of the differences in dietary estimates. The estimated average median daily dietary intake of ^{210}Po for adults is 0.16 Bq corresponding to an annual effective dose of 70 μSv.[268] The main sources of ^{210}Po in the human body are food and cigarette smoke; the body burden of ^{210}Po is relatively high in smokers with high-protein diets of seafood or meat (e.g., reindeer, caribou).[274] Bioaccumulation of ^{210}Po is higher in aquatic than terrestrial environments, with activity concentrations in fish reaching 1 Bq/kg and ~40 Bq/kg in mollusks. ^{210}Po binds easily to proteins in protein-rich foods (e.g., crustaceans, shellfish) containing relatively high concentrations of ^{210}Po activity.[275] ^{210}Po accounts for a substantial portion of the α-radiation in some marine organisms (i.e., up to 75% in mussels from the Cumbrian coast).[276] The estimated annual effective dose of ^{210}Po from the ingestion of caribou meat in the Northwest Territories of Canada is ~0.3–0.4 mSv.[277]

Lifestyle

The leaves of various plants contain ^{210}Po, including tobacco. In a study of popular Italian cigarettes, the ^{210}Po activities ranged from 6.84–17.49 mBq/cigarette.[278] The long interval between tobacco harvest and cigarette production (i.e., up to 6–7 half-lives of ^{210}Po) and the volatilization of this radionuclide at temperatures of >500°C reduce some ^{210}Po in tobacco smoke, resulting in the inhalation of ~1/3 of the ^{210}Po in a cigarette.[279] Cigarette filters do not adsorb significant amounts of ^{210}Po (i.e., mean = ~14%).[278] Based on studies of the ^{210}Po content of cigarettes, the estimated annual mean effective dose for 1-ppd smoker ranges from ~35–193 μSv.[279,280] A study by the National Council on Radiation Protection and Measurements indicates ^{210}Po in smoke accounts for ~2.8 mSv of the total average exposure of the US population (~6.5 mSv). The estimated mean annual effective doses for ^{210}Po in the country with the highest prevalence of tobacco smoking (Serbia) was 724 μSv,[281] whereas the estimated mean annual committed effective dose of ^{210}Po for a Japanese smoker consuming 20 cigarettes daily was 68 ± 27 μSv.[282]

DOSE-RESPONSE

Polonium is one of the most toxic natural radioactive isotopes because of radiation-induced injury to internal organs from the high specific activity (144 GBq/mg) and the emission of high-LET α-radiation (E_α = 5.3 MeV). Although estimating a fatal ^{210}Po dose is difficult because of various uncertainties (e.g., absorption, chemical form), modeling and existing data suggest a fatal dose is 10–30 μg in the absence of medical care.[261] Estimates of the ^{210}Po dose ingested by Alexander Litvinenko reflect this uncertainty.[263]

TOXICOKINETICS

Absorption

The risk of internal contamination results from ^{210}Po ingestion, inhalation, or contaminated wounds. Estimates of the absorption of ^{210}Po from the intestine are variable with a range of ~10–80% depending on speciation, solubility, pH, form (e.g., colloid), and complexation with other substances.[283,284] In a study of five volunteers ingesting 10 Bq ^{209}Po, the average uptake fraction by the gastrointestinal tract was 0.46 ± 0.08.[285] The ICRP initially used a low estimate (i.e., 10%) of gastrointestinal absorption of ^{210}Po,[25] but subsequently the ICRP raised this estimate to 50% based partly on an average gastrointestinal absorption of ~80% in six British volunteers ingesting naturally occurring ^{210}Po from brown crab meat.[284] The intermediate solubility (i.e., 50%) of ^{210}Po is supported by volunteer studies.[286] In a study of 14 volunteers ingesting naturally occurring ^{210}Po from caribou meat, the mean gastrointestinal absorption factor was 56% ± 4% with a range of 31–71%.[287] Dermal ^{210}Po absorption is minimal because of the inability of this radionuclide to penetrate the stratum corneum; consequently, external contamination does not produce radiation sickness when the skin remains intact.[261]

Distribution

Nonhuman primate studies on the intravenous administration of ^{210}Po indicate a rapid distribution phase that results in the disappearance of ~80–90% of the administered dose within 10–40 minutes.[288] The second elimination phase of ^{210}Po from the blood is much slower with a biological half-time of ~10–40 days. The distribution of ^{210}Po differs from other α-emitters (e.g., plutonium, uranium), which distribute primarily to the bone surfaces.[289] ^{210}Po is distributed from the blood primarily to soft tissues, with the highest concentrations occurring in the reticuloendothelial system (e.g., spleen, bone marrow, liver) and the kidney.[288] The estimated distribution of ^{210}Po in the human body in these organs is approximately as follows: liver, 30%; red bone marrow, 10%; kidney, 10%; and spleen, 5%.[290] Distribution to the skeleton is ~5% of the absorbed dose.[261] Typical concentrations of ^{210}Po in bones range from ~2–9 Bq/kg.[291] Animal studies suggest fetal transfer of ^{210}Po is relatively low.[1]

Elimination

Fecal excretion is probably the main route of ^{210}Po elimination from the body. Following the accidental inhalation of ^{210}Po oxide, fecal/urine ratios of ^{210}Po exceeded 10–20, especially during the first 20 days after exposure.[292] Although the typical estimated biological half-life for the elimination of ^{210}Po from the body ranges up to ~1–2 months, some studies of volunteers ingesting naturally occurring ^{210}Po in food suggest the retention half-life may exceed 100 days.[287] Figure 41.3 displays the urinary excretion of a 1 MBq dose of ^{210}Po with background rates for nonsmokers and smokers illustrated by solid and dotted lines, respectively.

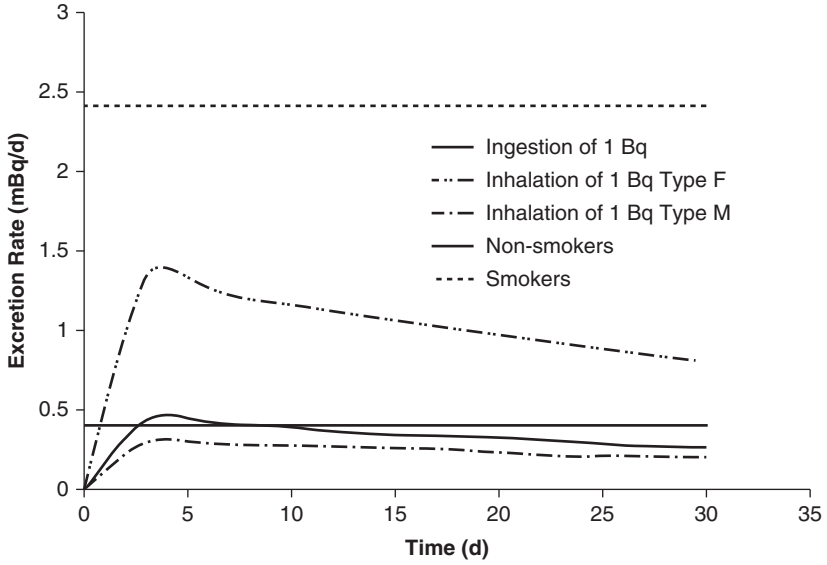

FIGURE 41.3. Daily urinary excretion of ^{210}Polonium (^{210}Po) after acute exposure to 1 Bq. (Redrawn from Anderson et al.).[293]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Maternal-Fetal Kinetics

Little specific human data on ^{210}Po are available with limited data from animal studies. Extrapolation of animal data to humans and predicted fetal radiation doses are complicated by difference in pharmacokinetics and organ development. In baboons administered intravenous ^{210}Po during the 5th month of pregnancy, the whole-body fetal/maternal ^{210}Po ratio was 0.3 with ~1% of the Po dose retained by the fetus.[208]

CLINICAL RESPONSE

Clinical effects from ^{210}Po exposure occur only after internal contamination because this radionuclide is an α-emitter with an extremely low abundance of photon emissions. Bone marrow syndrome, gastrointestinal syndrome, and local skin damage occur rarely following contamination by ^{210}Po, exclusively after very high ^{210}Po doses. The prodromal symptoms (e.g., nausea, vomiting, diarrhea, anorexia) are common, nonspecific gastrointestinal symptoms. For acute ^{210}Po exposure, bone marrow failure is the expected short-term effect of the ingestion of 2 GBq ^{210}Po based on dose estimates, lethal dose values, and an absorption fraction of 10%.[261] The clinical features of radiation-induced bone marrow failure are similar to those of bone marrow failure from other etiologies (e.g., drugs, infections, toxins).[261]

Figure 41.4 is a schematic timeline of the clinical effects of the poisoning of Alexander Litvinenko by ^{210}Po-tainted tea.

Although there is sufficient evidence of ^{210}Po carcinogenicity in experimental animal studies, human data are inadequate including cohorts of workers in the nuclear industry.[1] In a cohort study of 4,402 Caucasian men exposed to ^{210}Po processing and Po–Be neutron sources from 1944–1974, mortality from cancer was not elevated (SMR = 1.01, 90% CI: 0.73–2.16) when compared with mortality rates for US Caucasian men.[294] Annual doses were estimated from annual cumulative doses rather than direct measurements, resulting in potential misclassification. The study detected no significant trends in mortality from all causes, all cancers, or any specific cancers.

DIAGNOSTIC TESTING

External methods for detecting radioactivity from ^{210}Po do not identify internal ^{210}Po α-radiation. Geiger–Muller detectors usually require special wand or sensor attachments to efficiently detect α-radiation. No surface detector accurately assesses total-body α-emitter burden because α-particles cannot penetrate tissues; therefore, confirmation of internal ^{210}Po requires testing of biological samples (e.g., 24-hour urine and fecal collections). Older methods of the radiochemical analysis of urine

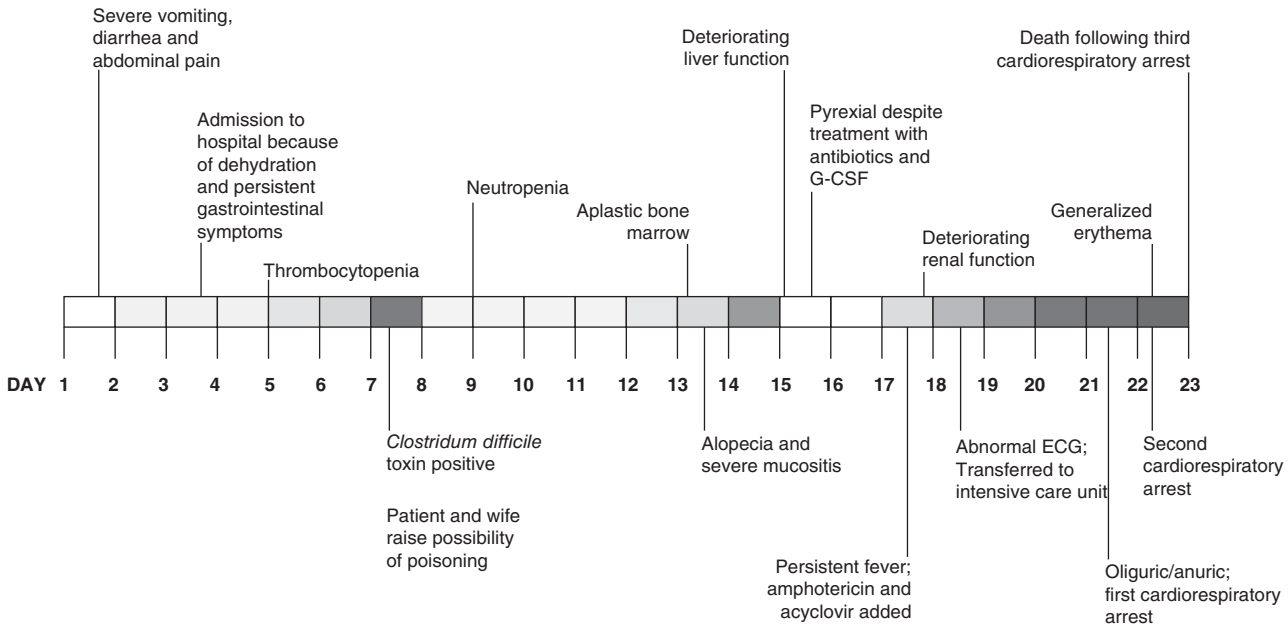

FIGURE 41.4. Schematic timeline of clinical features of ^{210}Polonium (^{210}Po) poisoning of Alexander Litvinenko. (Nathwani et al.).[264]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

sample for ^{210}Po used spontaneous deposition of this radionuclide following the direct application of raw urine to an appropriate metal disc (e.g., Ni, Cu, Ag). Subsequent studies indicated this method underestimated the amount of ^{210}Po when compared with the addition of ^{210}Po tracer to urine samples.[295] The volatility of polonium at temperatures of >100°C necessitates the use of wet-ashing techniques as part of sample preparation.[296] Following deposition of the sample on a suitable metal (e.g., silver, stainless steel), quantitation involves α-spectrometric analysis with silicon surface barrier/passivated implanted planar silicon (PIPS) detectors.

The estimated committed (50-year) effective dose equal to 250 mSv for the ingestion of ^{210}Po activity is 1.02 mBq.[293] This dose is substantially below the dose (14 mBq) associated with potential deterministic effects. A single-void urine specimen is sufficient to detect ^{210}Po activity above recommended standards during radiological emergencies.

TREATMENT

Patients with ^{210}Po contamination are not a health threat to medical responders. If polonium is present, excreta should be surveyed with α-detecting probe and handled per local radioactive waste disposal protocols. There are few human data on the use of chelating agents to enhance the excretion of ^{210}Po.[297] Animal studies suggest that dimercaprol (BAL), penicillamine, and DMSA are potential chelation agents, but the effectiveness of these agents decreases substantially following delayed administration.[298,299] Most evidence involves animal studies that administer the chelating agent soon after exposure and use higher chelating doses than typically administered in humans. Although some rodent studies demonstrate decreased blood ^{210}Po concentrations and increased survival with long-term therapy, other animal studies indicate increased retention in the kidneys and occasionally the brain and liver. The US Department of Health and Human Services (Radiation Emergency Medical Management, US Department of Health & Human Services) recommends 2.5 mg dimercaprol/kg qid × 2 days (days 1–2), then bid × 1 day (day 3) and qd (days 4–10). Newer potential chelating agents include mono-*N*-(*i*-butyl)-*meso*-2,3-dimercapto succinimide and mono-*i*-amyl-*meso*-2,3-dimercapto succinate. Although these two agents increase the total excretion of ^{210}Po, only the former compound reduces the concentration of ^{210}Po in the kidneys.[300] Neither DTPA nor EDTA was an effective chelation agent.[301]

RADIUM

HISTORY

The Curies discovered radium in 1898 while investigating uranium and pitchblende composition. Physicians in the early 20th century used radium for a variety of ailments including tuberculosis, skin lesions, cancer, arthritis, cancer, and digestive ailments, particularly before the Pure Food and Drug law was enacted in 1906. In 1902, William Hammer synthesized luminous paint by combining radium with zinc sulfide; by the time of World War I, radium paint was a constituent of watches and military instruments. Subsequently, young female radium dial painters were some of the first victims of industrial radiation poisoning.[302] In the early 1920s, ^{226}Ra and ^{228}Ra in triple-distilled water were advertised constituents of a patented radioactive medicine (i.e., Radithor) used as a metabolic stimulant and aphrodisiac. Although many patients lived years after long-term consumption of this substance, the death of Pittsburgh industrialist Eben M. Byers from an estimated dose equivalent of 350 Gy radium led to the removal of Radithor from the marketplace.[303] By the end of the 1920s, osteonecrosis of the jaw was a recognized occupational disease of radium dial workers.[304] Accumulating evidence of adverse effects from radium dial painting and subsequent lawsuits during the 1930s resulted in the passage of radium exposure standards in 1941. Luminous paints on watches and clock dials contained radium until the 1960s.

PHYSICOCHEMICAL PROPERTIES

Of the 16 known isotopes of radium, only 4 isotopes occur naturally (^{223}Ra, ^{224}Ra, ^{226}Ra, ^{228}Ra). ^{223}Ra, ^{224}Ra, and ^{226}Ra are α-emitters, whereas ^{228}Ra emits β-particles. ^{224}Ra has a short physical half-life (3.62 days); adverse health effects from exposure to this radionuclide result from its association with ^{228}Ra by the decay of ^{228}Th. Table 41.23 lists the physical properties of natural radium isotopes.

TABLE 41.23. Physical properties of natural radium isotopes.

Physical Property	^{223}Ra	^{224}Ra	^{226}Ra	^{228}Ra
Decay mode	α-particle	α-particle	α-particle	β-particle
Decay energy (MeV)	5.979	5.789	4.870	0.045
Half-life	11.4 days	3.6 days	~1,600 years	5.7 years

The solubility of radium salts increases with increased pH. Soluble radium compounds include bromide, chloride, iodate, and nitrate salts, whereas insoluble radium compounds include carbonate and sulfate salts. Table 41.24 lists the physiochemical properties of radium.

EXPOSURE

Radium is a ubiquitous radionuclide that occurs because of the radioactive decay of uranium and thorium. Radium does not hydrolyze or oxidize; therefore, this element does not undergo biodegradation in the environment. Low concentrations of radium isotopes exist in soil, rocks, food, and water; however, groundwater in some US regions contains radium concentrations exceeding the federal standard of 5 pCi/L.[306] In a German study of 582 public drinking-water samples, the radiation dose from ^{226}Ra ranged from <0.8–350 mBq/L with a median of 5.6 mBq/L and a 95th% of 41 mBq/L.[307] For ^{228}Ra, the concentration ranged from <0.7–120 mBq/L with a median of 4.6 mBq/L and a 95th% of 26 mBq/L. Radium was the most abundant radioactive contaminant in solids collected from drinking-water distribution systems during routine fire hydrant flushing in four US states (Illinois, Minnesota, Texas, Wisconsin); the total radium concentration ranged from 3.3–592 pCi/g with a mean of 143 ± 136 pCi/g.[308] The ^{226}Ra concentrations ranged from 2.7–250 pCi/g with a mean of 74 ± 68 pCi/g, whereas the ^{228}Ra concentrations ranged from 0.4–351 pCi/g with a mean of 69 ± 75 pCi/g.

Compared with groundwater, air is not an important radium source for the general population. The leaching of uranium mine tailings and release of ore-processing effluents are important causes of well water contamination with radium.[305] On a global scale, the amount of radium released into the environment from industrial use is insignificant compared with the natural occurrence of radium.[305] Radium is a radiation source for neutrons and radon in research, industrial radiography, and cancer treatment. Potential occupational sources of ^{226}Ra and ^{228}Ra include offshore oil extraction, coal mines, fossil fuel processing, blast furnace slag, and phosphate ores.[309]

TOXICOKINETICS

Absorption

The amount of radium absorbed after inhalation depends on solubility of the salt and particle size. The ICRP model and limited experimental data suggest most radium compounds are moderately absorbable (i.e., ~10–20%). Following accidental exposure to ^{226}Ra sulfate, the average retention half-life in the lung was ~120 days.[310] In a study of elderly human volunteers, ~20% of an oral dose of $^{224}RaSO_4$ was absorbed and distributed to the skeleton.[305]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Distribution

Depending on the solubility of the salt, inhaled radium is distributed to soft tissue and eventually to the skeleton. Soft tissue retention of ^{226}Ra peaks at 58% of the absorbed dose 18 days after a single ingestion with equilibration occurring at ~5% after 3 years.[311] Like calcium, radium deposits preferentially in areas of new bone formation, initially adsorbing into bony surfaces and red marrow followed by incorporation into the bony matrix. Hence, uptake into bone is much greater in growing than in mature bone. Chronic radium intake and bone remodeling eventually result in the uniform distribution of radium in the bone.[312] Although ^{224}Ra decays quickly with no residual radioactivity in the bone, ^{226}Ra persists in the bone because of its relatively long half-life compared with ^{224}Ra.[313]

Elimination

Most ingested radium is excreted in the feces probably involving biliary excretion. In dogs, the fecal to urinary excretion ratio of soluble radium salts following parenteral administration was 10:1.[314] Elimination of a parenteral radium dose in humans is slow with retention dropping from 2.5% of the original dose of radium at 1 year to 0.43% at 30 years.[315]

CLINICAL RESPONSE

An elevated incidence of cataracts occurred in radium dial painters and ~6% of children administered intravenous ^{224}Ra.[316] Additionally, these children frequently developed extensive resorption of the dentine, radiation-induced caries, and fractures of the teeth.[305] Although the incidence of bone marrow failure was slightly increased (10 cases vs. 7 cases expected), the statistical significance of this number of cases is unclear.[317] Ingestion of a radium-containing patent medicine, Radithor, was associated with headaches, toothaches, tooth loss, multiple areas of skeletal and soft tissue necrosis, bone marrow dyscrasia, multisystem failure, and death in the 1930s.[318] Diffuse interstitial fibrosis is a recognized complication of radiotherapy.[319] Occupational exposure to α-emitting radium in dust from fluorescent paint has been associated with the development of diffuse pulmonary fibrosis.[320]

Carcinogenesis

The IARC classifies ^{224}Ra, ^{226}Ra, and ^{228}Ra and their decay products as Group 1 (carcinogenic to humans) carcinogens.[1] Health effects following radium exposure result from the emission of α- and β-particles along with γ-radiation released during decay of radium and its daughter products including radon. The best-studied cohorts of radium-induced cancers are radium watch-dial painters (luminizers) and tuberculosis and ankylosing spondylitis patients treated with radium. Watch-dial paint contained the α-emitter ^{226}Ra and the β-emitter ^{228}Ra in zinc sulfide, whereas ^{224}Ra was the α-emitter in the intravenous German medication (Peteosthor) used to treat ankylosing spondylitis and tuberculosis from 1948–1975. In the dial industry, the ratio of ^{226}Ra/^{228}Ra in radium dial paints varied by company and time of use. Studies of US watch-dial painters demonstrated a consistently increased risk of bone sarcoma related to ingesting relatively high radium doses during the formation of finely pointed tips on the paint brush tips with their lips; the incidence of these tumors was particularly increased in women with active bone growth. The risk of bone sarcomas was not increased in British radium dial painters receiving a much smaller radium dose (i.e., estimated annual median endosteal bone surfaces and red marrow doses of 10 mGy and 1 mGy, respectively) because they did not use the pointing technique.[321] Over 900 German patients received intravenous ^{224}Ra for the treatment of tuberculosis and ankylosing spondylitis; the average absorbed radiation dose was 2 Gy to red marrow and 4 Gy to skeletal bones, with the mean bone surface dose reaching 30 Gy in the high-dose group.[322] Studies of this cohort indicated that bone sarcomas developed at radium doses of >1.03 μCi ^{224}Ra/kg.[323]

There is some evidence of an increased incidence of leukemia in the German cohort; however, a causal link between radium radionuclides and cancers other than bone sarcomas and head carcinomas is not well-established. The German studies suggested an elevated incidence of kidney, liver, breast, thyroid, and soft tissue cancers following intravenous ^{224}Ra doses.[324] The estimated mean absorbed dose from α-particle radiation was 0.56 Gy to the marrow-free skeleton of a 70-kg man with a mean bone surface dose of ~5 Gy. An increased incidence of breast cancer occurred in women receiving >12 μCi ^{224}Ra/kg intravenously before the age of 21 years.[325] All the patients in these studies were adults, in contrast to the many children and adolescents given Peteosthor in earlier studies. A follow-up study of 1,471 ankylosing spondylitis patients treated with intravenous ^{224}Ra did not confirm the elevated incidence

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of breast or liver cancer; however, the standardized incidence rates (SIR) for kidney (SIR = 1.98, n = 18, expected 9.1) and thyroid (SIR = 3.33, n = 4, expected 1.2) cancers were elevated.[326] The incidence of breast cancer and multiple myeloma was elevated in female radium watch-dial workers;[327] however, the large number of nulliparous women and exposure to γ-irradiation from ^{228}Ra paints are potential confounding effects.[328] A study of 274 Finnish residents exposed to radium in drilled wells for ~20 years did not detect an elevated hazard ratio of bladder or kidney cancer including no dose-response relationship between radium exposure and bladder or kidney cancer.[329] Overall, these studies involved small case numbers and lacked data demonstrating a dose-response relationship between radium exposure and cancer rates.

Osteosarcoma

US radium dial workers (luminizers) exposed to ^{226}Ra (α-emitter, $t_{½}$ = ~1,600 years) often along with ^{228}Ra (β-emitter, $t_{½}$ = 5.75 years) during radium dial painting developed an excessive incidence of bone sarcomas (osteogenic sarcoma, fibrosarcoma) and head carcinomas (paranasal sinuses, mastoid air cells). The bone sarcomas were widely distributed throughout the skeleton. Hazard modeling using multivariate analyses of dose-response relationships indicated both radium isotopes significantly contributed to the rate of bone sarcoma mortality; however, only ^{226}Ra was associated with mortality from paranasal sinus and mastoid air cell carcinomas.[330] ^{228}Ra decays to the noble gas ^{220}Rn (thoron) with a half-life of ~55 seconds. Examination of dose-response relationships in radium watch-dial painters indicates workers with high ^{228}Ra doses did not develop an increased incidence of carcinomas of the paranasal sinuses or mastoid processes. In a case series of 32 radium-induced cancers, the histological type of carcinomas was mostly soft tissue cancers, primarily mucoepidermoid (i.e., 8/21 mastoid; 4/11 paranasal sinuses) or epidermoid (12/21 mastoid, 3/11 paranasal sinuses).[331] The median tumor induction time from the first radium exposure to the first clinical feature of the tumor was 33 years for mastoid tumors (range, 21–50 years; n = 21) and 34 years for paranasal sinus tumors (range, 19–52 years; n = 11). Hazard modeling, histological subtypes, and association with ^{226}Ra suggest radium-induced paranasal sinus and mastoid carcinomas probably result from migration and entrapment of radon, the gaseous decay product of ^{226}Ra within these structures at relatively high doses (i.e., >12 μCi ^{226}Ra/kg).[305] These two cancers were not associated with internally deposited ^{228}Ra.

Evidence for elevated cancer rates following exposure to typical environmental radium concentrations is weak. A population-based case-control study of 238 cases of osteosarcoma from the Ontario cancer registry and 432 controls detected a weak, statistically nonsignificant association (OR = 1.31; 90% CI: 0.76–2.24) between lifetime measures of ^{226}Ra exposure in drinking water and osteosarcoma; there was no dose-response trend with increasing radium exposure.[332] The pooled analysis of 1,293 subjects from two Ontario studies for osteosarcoma was 1.44 (90% CI: 1.01–1.87) with a geometric mean absorbed dose of ~26 mrad (0.26 mGy). An ecological, population-based, case-control study of Wisconsin drinking water sources did not detect a significant association between the occurrence of osteosarcoma and median radium concentrations (OR = 0.98, 95% CI: 0.93–1.04, P = 0.56).[333] Residential ZIP codes were the basis of radium exposure estimates.

Leukemia

Analysis of the German cohort of patients receiving intravenous ^{224}Ra for ankylosing spondylitis detected an elevated risk of leukemias (observed, 21; expected, 6.8; $P < 0.001$), particularly myeloid leukemia. Although not typically associated with radiation, the incidence of chronic lymphatic leukemia was also elevated (observed 7; expected 2.4; P = 0.01). A statistically significant increased incidence of leukemia was not demonstrated in epidemiology studies of US or UK radium watch-dial workers who were administered smaller intravenous ^{224}Ra doses than the German patients.[334,335,336] The occurrence of leukemia was increased in a cohort of 899 German patients receiving high dose ^{224}Ra (mean bone surface dose, 30 Gy) with 8 leukemia cases observed and 3.8 cases expected (P = 0.04); however, the statistical significance of this value became nonsignificant when a 2-year lag period was applied (P = 0.08). Small case numbers and lack of dose-response data limit conclusions regarding causality.

Similarly, no definite causal connection was established in ecological studies of radium contamination in groundwater and an increased leukemia incidence. A study found a standardized incidence density ratio of 2.0 for the incidence of acute myeloid leukemia in counties with contaminated wells compared with the incidence of acute myeloid leukemia in counties without contaminated wells.[337] Contamination was defined by the presence of >5 μCi radium/L water in >10% of the wells. Misclassification and confounding complicate the interpretation of this study because of the lack

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of individual exposure data or data on other etiological factors for leukemia. A similar study of radium contamination in drinking water from 59 Iowa towns demonstrated a weak but statistically nonsignificant relationship between radium contamination and the incidence of leukemia.[338]

Reproductive Abnormalities

Studies in animals suggest high radiation doses cause a reduction in fertility by oocyte depletion. In a study of female workers in the radium watch-dial industry, radiation produced effects on fertility only at estimated cumulative ovarian dose equivalents >5 Sv.[339] These women were exposed to α-particles from ^{226}Ra and ^{228}Ra. At these high doses, internally deposited radium reduced fertility rather than inducing sterility.

TREATMENT

Medical management of acute radium exposure primarily involves reduction of gastrointestinal and bone absorption; recommendations are anecdotal with little experimental or clinical data to support specific recommendations. Recommendations include magnesium sulfate as an oral dose of 15 g magnesium sulfate in 100 mL of water or aluminum hydroxide in 60–100 mL water orally as a single adult dose. Barium sulfate (100 g $BaSO_4$ in 250 mL water PO) is an alternate therapy to reduce radium absorption. There are few data on the use of calcium gluconate (10 mL IV once or twice daily) to displace radium. Once absorption and deposition of radium occur in the bones, no specific antidotal therapy is effective.

RUTHENIUM

PHYSIOCHEMICAL PROPERTIES

Ruthenium (Ru) is a rare-earth, transitional metal (Group VIII with iron and osmium) that has a molecular weight of 101.7 g/mol, density of 12.45 g/cm^3, and melting point of 2,334°C. The chemistry of ruthenium is very complex with multiple oxidation states (2–4, 6–8) forming many inorganic cationic/anionic hydroxyl and halogen complexes in sulfide, chrome, and iron ores. The trivalent and tetravalent states (e.g., ruthenate) are the most stable. Most ruthenium radioisotopes are short-lived.

EXPOSURE

Occupational or environmental ruthenium exposure occurs primarily due to the longer-lived fission products from nuclear reactors and explosions, particularly ^{106}Ru (physical $t_{½}$ = 373.6 days, relatively high-energy β-emitter) and ^{103}Ru (physical $t_{½}$ = 39.3 days, β- and γ-emitter). In the nuclear fuel cycle, ruthenium usually exists as ruthenium tetroxide (RuO_4) vapor that can penetrate porous materials. Small quantities of ^{106}Ru and ^{103}Ru were detectable in the environment following the nuclear explosion at Chernobyl.[340] ^{101}Ru is a stable tracer of the isotope in blood samples. Ruthenium-based anticancer agents (e.g., NAMI-A, KP1019) are investigation drugs for the treatment of metastatic lung and neuroendocrine tumors as substitutes for platinum salts.[341]

TOXICOKINETICS

Inhaled RuO_4 vapors deposit mainly in the nasal passages and mouth; retention of a portion of these vapors as poorly soluble metallic ruthenium or ruthenium dioxide may occur for days to weeks. The reduction in radiation exposure depends on both the physical (radioactive, λp) and biological half-lives (λb) expressed as an effective half-life (λe) for the isotope in the body as displayed in Equation 41.3.

The effective half-life of accidentally inhaled air containing $^{103}RuO_4$ was ~10 days,[342] whereas the effective half-life of $^{106}RuCl_3$ administered orally and parentally to several animal species (mice, rats, monkeys, dogs) ranged from 15–50 days.[343] In a study of seven individuals monitored by external counting following accidental inhalation of airborne ^{103}Ru (possibly in the form of $^{103}RuO_4$ vapors and particulate ^{103}Ru), the biological half-time averaged ~80 days (λe = ~26 days) with a range of 64–93 days.[344] This isotope appeared in the urine and feces. Human volunteer studies with stable Ru isotopes indicate gastrointestinal absorption of sparingly soluble ruthenium radionuclides is low (i.e., <1–5%).[345,346] Limited data in humans suggest that the initial biological half-times are relatively short (several days) followed by a second component with a longer half-time (30–32 days).[347] Rodent studies suggest ^{106}Ru is poorly absorbed and rapidly eliminated, with no affinity for specific organs other than the kidney.[348]

TREATMENT

The NCRP prefers DTPA as a chelator with calcium disodium EDTA as an option;[72] however, there are inadequate clinical data to guide therapy.

STRONTIUM

PHYSIOCHEMICAL PROPERTIES

Strontium is an alkaline earth element along with calcium, magnesium, radium, and barium that is chemically reactive and easily oxidizes; the physiochemical properties of strontium in the body are similar to calcium. Of the 16 strontium isotopes, 6 are uranium fission products; ^{90}Sr is the most important Sr radionuclide from a health perspective as a result of a physical half-life of 29.1 years. The four stable isotopes are ^{84}Sr, ^{86}Sr, ^{87}Sr, and ^{88}Sr. ^{90}Sr is a relatively high-energy, pure β-emitter that decays to short-lived yttrium-90; ^{90}Y also emits a high-energy β-particle during decay.

EXPOSURE

^{90}Sr is primarily an anthropogenic radionuclide as a constituent of fission products from nuclear reactors and nuclear weapons. The long half-life and good gastrointestinal absorption (f_1 value = 30%) of ^{90}Sr result in serious radioactive contamination from fallout after a nuclear reactor meltdown or reactor core breach (e.g., Chernobyl). Two accidents at the Mayak plutonium production plant in the Soviet Union released substantial amounts of fission products into the Techa River between 1949 and 1957. Contamination levels exceeded 0.01 Ci ^{90}Sr/km^2 over 23,000 km^2.[349] Of the 38 villages in this area, 4 remained habitable. ^{85}Sr is a tracer in medical and agricultural research. ^{99m}Tc completely replaced the use of Sr in skeletal scintigraphy.

Treatment of metastatic bone pain includes radioisotopes, bisphosphonates, hormone therapy, chemotherapy, radiotherapy, surgery, and analgesia. ^{89}Sr chloride is a β-emitter used to control pain from metastatic bone cancer; a 2011 Cochrane review demonstrated some evidence ^{89}Sr provided complete reduction in pain over 1–6 months without increased analgesic use; however, serious leukocytopenia and thrombocytopenia were frequent in the 15 clinical studies evaluated.[350] ^{90}Sr is a power source for space vehicles and navigational beacons.

TOXICOKINETICS

The lungs and gastrointestinal tract rapidly absorb most soluble ^{90}Sr (e.g., carbonate, chloride, sulfate salts) with subsequent distribution primarily to active red marrow.[85] Systemic absorption of ^{90}Sr after ingestion is ~25% compared with ~33% after inhalation with mean values ranging from 15–45%.[25,177] In a study of Sr absorption of strontium from real and simulated fallout by 10 volunteers, the estimated mean absorption rates were 3% (range, 0–9%) and 16% (range, 6–25%), respectively. The mean estimated absorption rate of $^{85}SrCl_2$ in this study was 17% (range, 8–34%).[117] Factors that increase strontium absorption in these studies include fasting and low dietary concentrations of calcium, phosphorus, and magnesium. ^{90}Sr is classified as inhalation class D (days) by the ICRP.

Strontium is a homologue of calcium resulting in an affinity of Sr for bone similar to that of radium; the skeleton contains almost all the Sr retained by the body with the initial deposition occurring on the bone surface and active red marrow followed by migration; some of the strontium deposited on the bone surface redistribute to plasma over the next few days, while other ^{90}Sr radionuclides migrate to nonexchangeable sites in bone minerals (calcium hydroxyapatite). The retention time of the latter Sr in bone is ≥20 years.[351] Human and animal data suggest the initial uptake of strontium and calcium by the skeleton is much greater in growing than in mature individuals.[352]

The body clears most ^{90}Sr (i.e., >50%) within a week after exposure, with small amounts remaining in the body after 1 year, primarily in the skeleton.[353] Biliary excretion and unabsorbed Sr in the feces account for most Sr elimination; however, the renal excretion rate of strontium is relatively greater than calcium because of the less efficient reabsorption of strontium by the renal tubules. Data from populations exposed to radioactive releases from the Mayak plutonium plant in the Southern Urals of Russia suggest elimination rates are age- and sex-dependent. In a study of 108 men and 81 women from the Techa River Valley >30 years of age and followed for 24 years, yearly Sr elimination in the men increased from 2.8–3.2% after age 55 years.[354] The Sr elimination rate in women increased after age 45 with the yearly rate increasing to 5.8% after the age of 60. Strontium passes the placental barrier; however, the transfer of strontium from the mother to the fetus is less efficient for strontium than calcium. In a study of 185 pregnant women drinking water from the Techa River contaminated by radioactive releases from the Mayak plutonium production facility from 1949–1956, ^{90}Sr in maternal skeletons during pregnancy and lactation were 1.5–2-fold greater than nonpregnant, nonlactating women with similar exposures.[355] Analysis of several stillborn fetuses from mothers of reproductive age exposed to contaminated Techa River drinking water

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

demonstrated fetal/maternal ^{90}Sr ratio in bone ranged from 0.21–0.26.[356]

CLINICAL RESPONSE

The International Agency for Research on Cancer (IARC) indicates the evidence is sufficient to classify strontium as an animal carcinogen (bone, lymphoid tumors)[357] along with other pure β-emitters (^{3}H, ^{32}P, ^{90,91}Y, ^{147}Pm).[1] Currently, the IARC considers that evidence for human carcinogenicity of ^{90}Sr is limited with a positive association between ^{90}Sr exposure and leukemia.[358] Dose-related increases in mortality rates from leukemia and solid tumors occurred in Russian populations in the Techa River Valley exposed to internal contamination predominantly from ^{90}Sr (i.e., ~90%) and external radiation released from the Mayak plutonium plant as fission products.[348]

DOSIMETRY

The best biomarkers for individuals exposed to atmospheric debris from nuclear weapons testing are urinary ^{90}Sr and ^{239,240}Pu concentrations above background global fallout levels.[359]

TREATMENT

Aluminum hydroxide antacids reduce the gastrointestinal absorption of strontium when given within several hours of ingestion. Barium sulfate is a low-risk alternative oral agent that reduces ^{90}Sr absorption when administered within 24 hours of exposure. The administration of strontium (daily oral dose of 500–1,500 mg strontium lactate or daily IV dose of 600 mg strontium gluconate up to 6 days) also enhances strontium excretion when administered soon after exposure. Intravenous calcium is an alternative to strontium gluconate that may also enhance ^{90}Sr excretion when given soon after exposure. Rodent studies do not support the efficacy of chelators for Sr removal from bone. After initiating treatment 24 hours after receiving the last of 20 subcutaneous injections over the preceding 4 weeks, none of the chelators improved outcome; chelating agents tested included DPTA, Kryptofix 5® (1,11-bis(8-quinolinyloxy)-3,6,9-trioxaundecane, CAS RN: 57310-75-5), and Kryptofix 222® (4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo(8.8.8)hexacosane; CAS RN: 23978-09-8; E Merck, Darmstadt, FRG).[360,361]

TECHNETIUM

PHYSIOCHEMICAL PROPERTIES

All technetium isotopes are radioactive. The metastable ^{99m}Tc decays to ^{99}Tc with a physical half-life of 6 hours by emitting a 0.14 MeV γ-ray easily detectable at a body surface. Within 24 hours, 93.7% of ^{99m}Tc decays to ^{99}Tc. Metastable means the nuclear isotope does not decay into another element. The physical half-life of ^{99}Tc is 212,000 years; therefore, this isotope has no adverse health effects from emitting radiation. Electrons emitted by ^{99m}Tc have a range of 50–70 cell diameters (<700 μm). Although the distribution of the radionuclide is not necessarily homogeneous, most energy from ^{99m}Tc decay deposits in this area.[362]

EXPOSURE

^{99m}Tc is the most common radioisotope in nuclear medicine for organ imaging, with ^{131}I being the second most common; technetium pertechnetate is the preferred compound for diagnostic procedures. Exposure to ^{99m}Tc occurs during the production of ^{99m}Tc with radionuclide generators and during injecting and imaging the patient while positioning the patient and the camera. A technetium-99m generator bombards a ^{98}Mo sample with neutrons and extracts the metastable isotope ^{99m}Tc from the radioactive decay of ^{99}Mo. This process allows the transport of short-lived ^{99m}Tc over long distances because the half-life of ^{99}Mo is ~66 hours. The internal radiation dose for personnel is typically lower than external exposures, with annual effective doses of <1 mSv;[4] the annual dose seldom exceeds 6 mSv.[363]

TOXICOKINETICS

The lungs and gastrointestinal tract absorb ^{99m}Tc rapidly and well (e.g., 70%). The biological half-life of ^{99m}Tc is ~1 day. The short physical half-life of ^{99m}Tc results in delivery of the radiation dose within hours after exposure. Animal studies suggest ^{99m}Tc selectively accumulates in the stomach, salivary glands, and thyroid gland; this radionuclide is nonbone seeking.[364] Following intravenous administration of technetium pertechnetate to volunteers, a 3-compartment model best describes whole-body Tc retention with half-times of 1.6 days (77%), 3.7 days (19%), and 22 days (4%).[365] The biological half-life of technetium pertechnetate is ~6 hours for the whole body compared with 20 days

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for the kidney and 30 days for the liver.[25] ^{99m}Tc is secreted in breast milk following injection; therefore, breastfeeding should be interrupted after ^{99m}Tc administration for 25 hours after administration of 80 MBq ^{99m}Tc-pertechnetate to prevent the infant from receiving an annual radiation dose of >1 mSv.[366,367]

CLINICAL RESPONSE

Although all types of ionizing radiation are human carcinogens, the IARC does not associate exposure to ^{99m}Tc with animal or human cancer.[1] Adverse reactions associated with the use of ^{99m}Tc are minor except rare anaphylactic reactions;[368] accidents involving ^{99m}Tc typically have not been associated with serious adverse effects.[25]

TREATMENT

Patients receiving ^{99m}Tc should be well hydrated and encouraged to urinate frequently after ^{99m}Tc administration. Potassium perchlorate displaces ^{99m}Tc from sites in the stomach, salivary gland, and thyroid gland; however, there are no human data to guide therapy. *In vitro* studies suggest DTPA chelates ^{99m}Tc in the tetravalent but not pentavalent oxidation state.[369] Data are inadequate to determine the efficacy of DTPA for chelation of ^{99m}Tc following internal contamination. The NCRP does not recommend chelation for the treatment of internal contamination by ^{99m}Tc.[72]

THORIUM

HISTORY

The Swedish chemist, Jons Jakob Berzelius, discovered thorium in 1828, naming the metal after the Norse god of thunder (Thor). The radioactivity of thorium was not demonstrated until 1898. In the early 1900s, the primary commercial use of thorium was as an incandescent constituent of gas lamp mantles. Umbrathor® was an oral, thorium-based radiological contrast agent originally introduced in Germany in the 1920s by the Heyden Chemical Company for imaging the gastrointestinal tract; this contrast agent produced excellent images and remained in aqueous solution with less risk of intestinal blockage than barium. Subsequently, Testagar and Company released a similar contrast agent, Thorotrast®, in 1931.[370] This injectable contrast agent was a colloid solution containing ~20–25% ^{232}Th dioxide stabilized by dextran. The agents were used worldwide throughout Europe, Japan, and North America until the 1950s. Thorotrast® was an excellent contrast agent for the visualization of cavities (e.g., nasal sinuses) and narrow canals (e.g., cerebral vessels); however, an iodine-based nonradioactive medium began replacing this agent in the 1940s because of the development of granuloma formation at extravasation site and the increased risk of bone marrow and liver cancer 20–30 years after use.[371] An estimated 50,000–100,000 patients received Thorotrast® worldwide,[372] typically in intravenous doses of 10–75 mL (129–962 Bq/kg or 3.5–26 nCi/kg).[373] This α-particle-emitting radionuclide remained in the body long after injection accumulating in the liver, spleen, and bone marrow.[374] Of the members of the German cohort receiving intravenous Thorotrast® and surviving the original reason for imaging, malignancies and liver cirrhosis accounted for ~40% of the deaths.[375] The effective radiation dose of Umbrathor® was substantially less than Thorotrast® because of the relatively limited gastrointestinal absorption of Umbrathor®.

PHYSIOCHEMICAL PROPERTIES

Thorium is a dense, relatively reactive, metallic element classified in the actinide series; all 12 isotopes are radionuclides that decay primarily with emission of α-particles and less commonly with β-particles and γ-rays to produce daughter radionuclides and eventually the stable elements, ^{206}Pb and ^{208}Pb. Daughter radionuclides include ^{228}Ra and thoron from ^{232}Th, whereas decay products of ^{230}Th include ^{226}Ra and ^{220}Rn. Of the 12 thorium isotopes, ^{232}Th is vastly more common in natural thorium (i.e., >99.99%) than all other Th isotopes; natural thorium contains very small amounts of ^{228}Th and ^{230}Th. ^{232}Th undergoes six α- and four β-disintegrations to form stable ^{208}Pb, as demonstrated in Figure 41.5. ^{230}Th (long-lived α-emitter) and ^{234}Th (short-lived β-emitter) are decay products of the ^{238}U series, whereas ^{227}Th and ^{231}Th are decay products of ^{235}U series. Only ^{228}Th, ^{230}Th, and ^{232}Th have sufficiently long half-lives to deposit environmentally significant amounts of radiation. Table 41.25 lists the energies and abundance of α- and β-particles emitted by thorium isotopes along with their physical half-lives.

The body retains most incorporated ^{232}Th and ^{234}Th (i.e., >90% at 3 weeks) because of their long physical and biological half-lives.[376] Water-soluble thorium complexes include chloride, fluoride sulfate, and nitrate salts, whereas carbonate, dioxide, hydroxide, oxalate, phosphate, and the salts are insoluble thorium compounds. Thorium exists in the body exclusively in the tetravalent oxidation state.

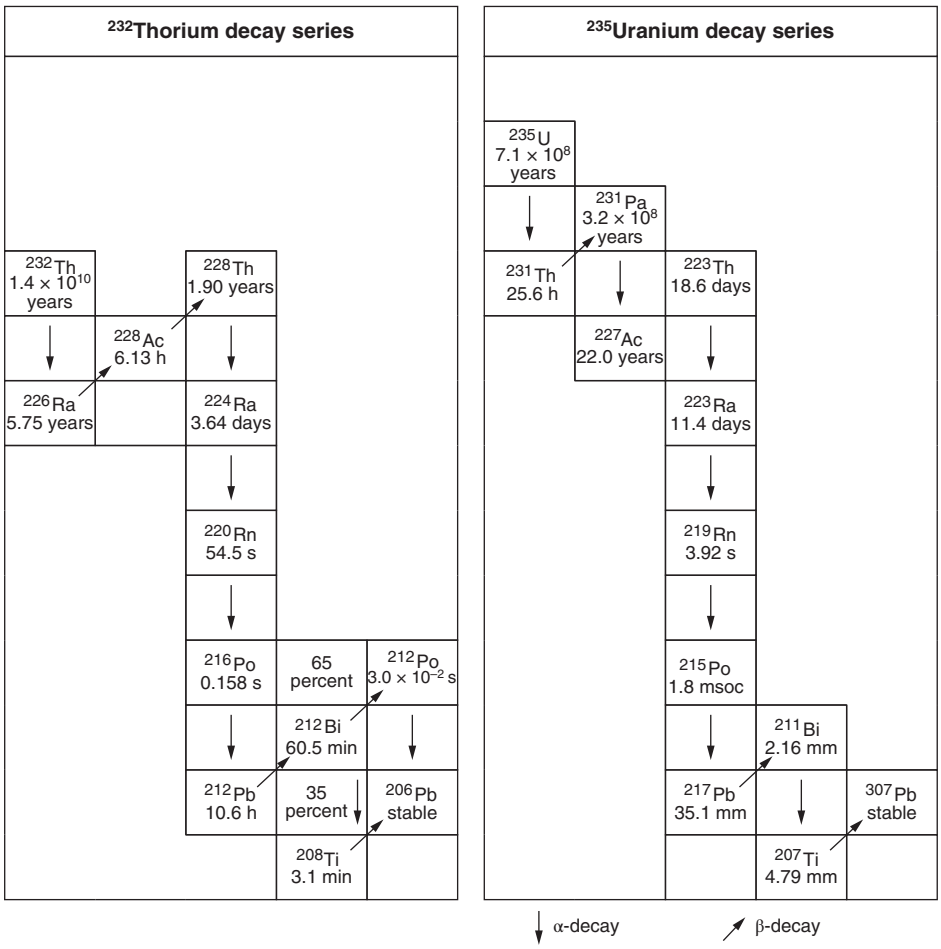

FIGURE 41.5. ^{232}Thorium and ^{235}uranium isotope decay series with subsequent decay products and half-lives. The ^{238}U decay series also produces thorium daughters as displayed in Figure 41.2.

Table 41.26 displays identifying characteristics and physical properties of thorium and thorium compounds.

EXPOSURE

In nuclear energy applications, the bombardment of ^{232}Th by neutrons and the emission of a β-particle produce the fissionable radionuclide ^{233}U that is fissile nuclear fuel for advanced heavy-water reactors. Thorium-containing ores include huttonite, monazite, thorianite, thorite, and thorogummite; these ores are more common than uranium ores. The primary commercial source of thorium is the separation of monazite as a by-product of the mining of heavy-mineral sands for titanium and zirconium. Potential occupational sources for ^{232}Th include processing of niobium or phosphate ores and production of gas mantles, high-intensity discharge lamps, and some welding rods.[309] In a study of five welding shops using thoriated electrodes during TIG welding, ^{232}Th levels in the breathing zone of the welders were generally <10 mBq/m^3.[377] The estimated annual committed effective dose from inhalation of ^{232}Th, ^{230}Th, ^{228}Th, and ^{228}Ra for a full-time TIG welder was <0.3 mSv; with conservative assumptions, the radiation dose was ≤1 mSv. A patient with a deposit of 1 μCi ^{232}Th in the reticuloendothelial system receives 0.2 Gy (20 rads) in the terminal bronchi over 10 years and 2.6 Gy (260 rads) over 10 years in the trachea.[378] After 30 years, the cumulative doses for the terminal bronchi and trachea are 0.8 Gy (80 rads) and 10 Gy (1,000 rads), respectively. The mean estimated annual radiation doses from the injection of 30 mL of Thorotrast® for specific locations in the spleen, liver, and bone are the following: 0.8 Gy (80 rads), spleen; 0.3 Gy (30 rads), liver; 0.15 Gy (15 rads), bone surface cells; 0.1 Gy (10 rads), red bone marrow; 0.048 Gy (4.8 rads), cancellous bone; 0.045 (4.5 rads), lungs; and 0.033 Gy (3.3 rads), compact bone.[379]

TABLE 41.25. Energies and occurrence of major α- and β-particles emitted by the 12 thorium isotopes (^{223}Th to ^{234}Th). In general, the severity of biological effects following exposure to ionizing radiations is proportional to the density of the ionization produced by their passage through tissue. α-Particles deposit all their energy within a very short distance producing dense ionization, whereas β-particles produce less ionization. The ionization density of γ-rays is less than α- or β-particles.

Thorium Isotope	α-Particle Energy (MeV)	Abundance (%)	β-Particle Energy (MeV)	Half-Life
223	7.287	60	—	0.66 seconds

234			0.270	24.1 days

ENVIRONMENTAL FATE

Even though most thorium isotopes are synthetically produced, over 99% of the thorium in the earth's crust exists as the isotope ^{232}Th in combination with various minerals (e.g., silica).[380] These complexes do not dissolve in water or evaporate into air; therefore, exposure to this natural isotope from environmental sources is very small. Windblown dust and volcanic explosions are the most significant natural thorium sources, whereas major industrial thorium sources include uranium and thorium mining, tin processing, coal-fired utilities, industrial boilers, and phosphate rock processing. Medically significant thorium exposure typically requires specific areas that contain excess quantities of thorium.

Although the existence of thorium in the environment is widespread, the thorium concentrations in air, soil, water, and foods typically are very low; the USEPA does not require the monitoring of drinking water for thorium concentrations. The estimated total daily intake of ^{230}Th and ^{232}Th ranges from ~0.02 to 0.17 pCi.[219] The average population-weighted concentrations of ^{232}Th and ^{230}Th in the water supply are 0.01 pCi/L and 0.04 pCi/L, respectively. The average daily intake of ^{232}Th and ^{230}Th by New York City residents was 0.11 pCi and 0.17 pCi, respectively.[381] Thorium was the second most abundant element contributing to total radioactivity of distribution solids collected in drinking-water distribution systems during routine fire hydrant flushing in four US states (Illinois, Minnesota, Texas, Wisconsin).[308] Total thorium exposure (^{228}Th, ^{230}Th, ^{232}Th) ranged from 1.2–100 pCi/g with a mean of 40 ± 25 pCi/g. ^{228}Th was the dominant radionuclide in 90% of the solid samples.

TOXICOKINETICS

Absorption

Pulmonary

The amount of thorium absorbed into the circulation by the lungs depends on the quantity of thorium reaching the alveoli (i.e., size of the particles) and the chemical properties (e.g., solubility) of the particular thorium compound. Ciliary clearance removes most inhaled thorium by expectoration and/or ingestion. Thorium dioxide usually remains in the lung for a long time. In experimental animal studies, 68–73% of ^{232}Th dioxide remained 1 day after intratracheal administration; 15–30% persisted for 21 months.[382] The ICRP model for thorium assumes the systemic circulation will absorb 5% of the thorium retained in the lung; however, pulmonary deposition of soluble thorium salts produces higher systemic absorption. In animal studies, inhalation of soluble thorium citrate and chloride salts resulted in absorption of 33% and 19% of the inhaled dose, respectively.[383]

Gastrointestinal

Although systemic Th absorption is generally higher for water-soluble than poorly soluble thorium salts, the gastrointestinal absorption of all thorium compounds is relatively low (~0.02%).[384] Animal studies indicate Th absorption of thorium from the intestine of the neonatal rat increases 40-fold more than adult rats, suggesting infants may be more susceptible to Th toxicity.[385] As a result of the low gastrointestinal absorption, inhalation accounts for ~2/3 of the systemic absorption of thorium based on epidemiology studies.[386]

Distribution

The maximum concentration of natural thorium isotopes occurs in the tracheobronchial lymph nodes with lesser amounts of thorium occurring in the lungs and bones. Based on animal data, modeling for "bone-surface-seeking" radionuclides, including thorium, suggests ^{228}Th deposits primarily on bone surfaces (~70%) with lesser amounts in the liver (4%) and soft tissues (16%).[387] Thorium deposits in the adrenals, intestines, kidneys, pancreas, and testes are

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

relatively minor.[388] In an autopsy study from the US Transuranium and Uranium Registry, the maximum ^{232}Th concentrations in individuals without occupational thorium exposure ranged from 20–400 ng/g in lung and from 160–400 ng/g in lymph nodes.[389]

In contrast to the distribution of natural thorium isotopes, the intravenous administration of stabilized thorium dioxide (Thorotrast®) in a colloidal form results in the distribution of thorium into the macrophages of the reticuloendothelial system (liver, 59%; spleen, 29%; bone marrow, 9%); thus, stabilized $^{232}ThO_2$ is not classified as a bone-seeking radionuclide.[379,390] The distribution of ^{232}Th in Thorotrast® to tissues was inhomogeneous because of the uneven uptake of the ^{232}Th-transferrin complex from the serum.

Elimination

Fecal elimination following ciliary clearance accounts for up to 97% of the inhaled thorium dose (i.e., primarily unabsorbed Th) after thorium exposure from uranium ore dust inhalation during uranium processing.[391] Biliary and renal excretion account for ~10% of the systemically absorbed Th dose.[387] The biological half-lives of ^{232}Th and ^{230}Th in the lungs of residents living near the tailings of a uranium mine were 5.3 years and 1.4 years, respectively.[386] For modeling retained particles in the lungs, the ICRP considers thorium a class Y (years) compound. Animal studies suggest ^{227}Th nitrate has relatively greater pulmonary clearance than ^{232}Th dioxide with a biological half-life of ~20 days.[392] The kidney excretes very small amounts (i.e., 0.7% of the dose within the first 17 days) of insoluble thorium compounds (e.g., ^{232}Th in intravenous Thorotrast®).[393] Relatively greater excretion occurs via the kidney for soluble thorium compounds (e.g., ^{234}Th citrate).

CLINICAL RESPONSE

Occupational Exposure

The IARC classifies ^{232}Th as a Group 1 (carcinogenic to humans) carcinogen based on the increased incidence of cholangiocarcinoma following the diagnostic use of Thorotrast®.[1] Initial epidemiology studies of workers exposed to thorium did not detect significant increases in cancer mortality at estimated radiation levels of 0.001–007 Bq/m^3 over 1–33 years.[394] In the original study of the thorium-processing cohort, an increase in the incidence of respiratory disease (33 vs. 25.2), lung cancers (31 vs. 21.6), pancreatic cancer (9 vs. 4.5), and rectal cancer (6 vs. 3.2) occurred; however, high rates of smoking and coexposures (e.g., silica) confounded the results. The estimated mean committed dose from thorium exposure was 5 μSv. A follow-up study at this thorium-processing and gas mantle production plant evaluating 3,796 workers beginning employment in 1940 and followed through 1982, demonstrated a significant increase in all malignant neoplasms (SMR = 1.23; 95% CI: 1.04–1.43) and lung cancer (SMR = 1.36; 95% CI: 1.02–1.78) for male workers, but not for female workers.[395] There was no dose-response relationship between duration of employment and cancer rates; smoking data on the cohort members remained unavailable.

A definite causal relationship between occupational thorium exposure and the development of cancer has not been established.[380] A study of tungsten inert gas welding workers using thoriated rods did not demonstrate significant increases in ^{232}Th uptake; there was no increase in mortality, morbidity, or reduced renal function (retinol-binding protein, β_2-microglobulin) in these workers compared with a control group.[396]

Diagnostic Use (Thorotrast®)

Follow-up studies of patients administered intravenous Thorotrast® (colloidal $^{232}ThO_2$) from 1928–1955 demonstrate significantly increased cancer mortality, primarily hepatobiliary cancer and leukemia. These studies are not directly applicable to occupational or environmental thorium exposures because of differences in dose, distribution, and toxicokinetics. Extravasation of Thorotrast® produces pain, swelling, induration, and abscess formation. Local granulomas develop at the site of injection within 4–6 years from fibrosis, nerve paralysis, and vascular changes. Malignant tumors (soft tissue sarcomas, squamous cell carcinomas, and lymphoepithelial carcinomas) may develop at the edge of the granuloma after 10–30 years.[370,397]

Deterministic Effects

Liver cirrhosis is the most common systemic effect of intravenous administration of Thorotrast®, with latency periods averaging 25–30 years.[380] In a study of 272 war-wounded Japanese servicemen who were administered Thorotrast® and followed for 35–43 years, 13 developed cirrhosis.[398] Hematological disorders frequently appeared many years (e.g., 17 years) after injection, including leukemia, aplastic anemia, myelofibrosis, hemolytic anemia, Di Guglielmo's syndrome,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

splenic fibrosis, and fatal purpura. Severe narrowing of the coronary arteries, myocardial infarction, and internal derangement of the carotid artery developed in two patients injected with Thorotrast® 21–30 years prior to examination.[372]

Stochastic Effects (Cancer)

Carcinogenic effects of Thorotrast® result from the accumulation of α-radiation rather than chemical effects of thorium or colloid. The National Toxicology Program lists thorium dioxide as a known human carcinogen based on the increased incidence of liver tumors (primarily cholangiocarcinomas and hemangiosarcomas) in patients given Thorotrast®.[399] The International Agency for Research on Cancer (IARC) classifies ^{232}Th and its decay products as human carcinogens based on the large increases in liver cancer (e.g., hemangiosarcoma) and leukemia (excluding chronic lymphocytic leukemia) following diagnostic injection of ^{232}Th as stabilized $^{232}ThO_2$ in colloidal form (Thorotrast®).[1] All studies of patients receiving Thorotrast® intravenously demonstrated an increased incidence of tumors of the liver and leukemia with relative risks of liver cancer incidence or mortality ranging from 36–129.[400] For liver cancer, leukemia, and gallbladder cancer in the European and American cohorts of Thorotrast® patients, the risks of developing these cancers increased with α-particle dose and duration of exposure.

Liver

In the German cohort of 2,326 patients with a history of intravenous Thorotrast® administration (primarily cerebral angiography) and 1,890 hospital controls, the overall mortality of men and women increased with SMRs of 2.87 (95% CI: 2.73–3.01) and 3.87 (95% CI: 3.57–4.19), respectively, assuming a control SMR of 1.0.[375] Cause-specific mortality from cancers of the liver and hematopoietic system increased dramatically, whereas lung cancer rates were not elevated. The German study began in 1968 after a substantial portion of the exposed and control groups died; additionally, some differences existed between the control and exposed groups including the control group being on average 4 years older, having smaller cohort size, and lacking injected contrast medium as well as the existence of potential differences in underlying disease between the two groups and selection bias in the follow-up group.

In contrast to the predominance of hepatocellular carcinomas (i.e., ~90%) in unexposed patients, the portions of hepatocellular carcinomas, hemangiosarcomas, and cholangiocarcinomas are similar in Thorotrast® patients.[401,402] In these studies, the incidences of liver and gallbladder tumors were dose-related to the cumulative radiation dose from intravenous Thorotrast®, with increased risks in patients receiving larger Thorotrast® doses.[403]

The approximate mean latency periods for hemangiosarcomas and cholangiocarcinomas were 33 years and 28 years, respectively, with most liver cancers appearing >20 years after exposure.[404] Individual case reports suggest the latency period for angiosarcoma, cholangiocarcinoma, and hepatocellular carcinoma of the liver may exceed 40–50 years.[405,406] Hemangiosarcomas are very rare tumors associated with exposure to vinyl chloride monomers, arsenic, and polychlorobiphenyls (PCBs). The increased incidences of hemangiosarcomas and cholangiocarcinomas reflect the nonhomogeneous distribution of ^{232}Th in the liver, with the bile ducts and periportal tissues receiving ~15 times greater radiation from deposited α-particles than hepatic cord tissues.[407,408]

Leukemia

The diffuse distribution of Thorotrast® in the bone marrow suggests that exposure to Thorotrast® can induce bone marrow failure and leukemia;[409] in studies of Thorotrast® patients from Denmark, Germany, Japan, Portugal, Sweden, and the United States, the risk of leukemia excluding chronic lymphocytic leukemia (CLL) increased compared with national rates. The relative risk (RR) of developing all leukemias excluding CLL in the combined Thorotrast® cohorts from Denmark and Sweden was 6.1 with a 95% CI of 0.8–35.6,[403] whereas the RR for leukemia in the extended follow-up of the Portuguese Thorotrast® cohort was 10.2 (95% CI: 1.24–471, $n = 6$ with no CLL cases).[410] Although the German cohort demonstrated a dose-response relationship between injected Thorotrast® volume and the leukemia risk, the Portuguese, Swedish, and Danish cohorts did not demonstrate similar trends.

Leukemia (primarily erythroleukemia and acute myelogenous leukemia) developed in Portuguese patients exposed to Thorotrast® after a latency period of 20 years;[400] this latency period is much longer than the usual latent period (<10 years) for the development of leukemia based on studies of the Japanese atomic bomb cohort receiving external ionizing radiation. A median 40-year follow-up study of children born to parents exposed to Thorotrast® did not demonstrate an association between parental exposure to radiation and the risk of childhood leukemia or lymphoma.[411] For the 226 children of exposed fathers, the SMR for cancer was 1.3 (95% CI: 0.5–2.9) compared with 1.4 (95% CI: 0.4–3.5) for 143 children born to mothers with a history of Thorotrast® injection. There was one case

of Hodgkin's lymphoma and no cases of leukemia or non-Hodgkin's lymphoma among the offspring.

DOSIMETRY

Conversion Factors

^{228}Th: 1 pCi = 1.2×10^{-9} μg
^{230}Th: 1 pCi = 48×10^{-9} μg
^{232}Th: 1 pCi = 9.1×10^{-9} μg
1 pCi = 10^{-12} Ci

Analytical Methods

α- and γ-Spectroscopy are traditional methods for detecting thorium in biological samples, whereas inductively coupled plasma/optical emission spectrometry (ICP/OES) is a sensitive measure of total thorium.[412] Neutron activation analysis measures ^{232}Th concentrations in the ng/L range (4×10^{-6} Bq/L),[413] whereas inductively coupled plasma/mass spectrometry (ICP/MS) is a sensitive technique for determining thorium isotopes including ^{232}Th concentrations in biological samples with a lower limit of detection in the range of ≤0.001 Bq/L.[414]

Biomarkers

The median daily intake of ^{232}Th in a study of Asian populations ranged from 0.6 mBq/L in the Philippines to 14.4 mBq/L in Bangladesh;[415] the United Nations Scientific Commission on Effects of Radiation (UNSCEAR) estimated a global intake value of 4.6 mBq for ^{232}Th. In a study of Australian mineral sand workers, the serum geometric mean thorium concentration was 480 ± 1.7 ng/L (range, 170–2,000 ng/L; $n = 25$) compared with a geometric mean of 320 ng/L for unexposed workers.[416] The geometric mean urine thorium concentration was 31 ng/L (range 3–210 ng/L; $n = 32$) in unexposed workers. Although neither serum nor urine concentrations correlated well with cumulative exposures, serum thorium concentrations were less variable than urine thorium concentrations.

Abnormalities

Plain X-ray radiographs of patients injected with Thorotrast® typically demonstrate opacification of the liver, spleen, and abdominal lymph nodes corresponding to the amount injected.[417] CT findings involve the presence of high-density deposits in the liver, spleen, and lymph nodes from deposition of ^{232}Th; splenic changes include atrophy from the fibrotic response to ^{232}Th deposition. Although multiphase contrast-enhanced CT and MR images of the liver may demonstrate early changes of ^{232}Th-induced tumors, the findings are nonspecific.[418]

Most,[419,420] but not all,[421] studies of Thorotrast® survivors demonstrate an increased frequency of stable and unstable chromosomal abnormalities when compared with age-matched controls. A statistically significant excess incidence of unstable chromosomal aberrations (dicentrics, centric ring) occurred in the pooled lymphocytes of higher body burden groups (mean = 0.56 ± 0.09 nCi) in a cohort of 47 male workers in a thorium processing plant, when compared with historical controls; the difference in 2-break chromosomal aberrations was not statistically significant.[422] The duration of employment did not correlate to the presence of chromosomal aberrations. A high incidence of chromosomal abnormalities developed in surviving Thorotrast® patients, including stable and unstable aberrations (e.g., dicentrics). In a study of eight long-term (mean = 47.4 years) Thorotrast® survivors and five controls (nonradioactive contrast medium only during the same era), the number of multicentric, centric, and acentric rings was statistically different ($P = 0.04$); the number of chromatid mutations as measured by hypoxanthine phosphoribosyltransferase (HPRT) was not different between the two groups.[423] Although dicentric chromosome aberrations occur in Thorotrast® patients, the number of chromosomal aberrations does not correlate to whole-body radioactivity.[424]

HEALTH SURVEILLANCE

The World Health Organization (WHO) guideline for individual thorium isotopes in water (^{228}Th, ^{230}Th, ^{232}Th) is 1 Bq/L.

TREATMENT

Ca-DTPA is the most effective chelating agent in animal studies; however, this chelator has only limited practical value because of the small amount of thorium removed from the body.[425] The NCRP lists DTPA as a suggested rather than preferred treatment.[72] Limitations of the effectiveness of free-DTPA result from its rapid urinary excretion (i.e., 90% in the first day) and difficulty penetrating cell membranes. In a study of rats injected with 0.6 mg thorium nitrate/kg and receiving either 11.2 mg DTPA/kg as free-DTPA or DTPA encapsulated in uncharged liposomes 6 hours later, the absorbed

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

thorium dose in the liver decreased from 42–33% after DTPA and to 22% after encapsulated DTPA.[426] Liposomal encapsulation increased the DTPA concentration and duration in the liver and blood.

TRITIUM

PHYSIOCHEMICAL PROPERTIES

Tritium (CAS RN: 10028-17-8, ^{3}H) is the only radioactive isotope of hydrogen; its molecular weight is 6.032 g/mol. This radionuclide has a physical half-life of 12.3 years, decaying by emission of a low-energy β-particle. The emitted electron has a range of energies up to 18.6 keV with a mean energy of 5.7 keV; the decay process includes an electron antineutrino. The maximum track length of the emitted electron is 6 μm in water (i.e., <average diameter of a cell) and ~6 mm in air; consequently, these particles cannot penetrate the outer layer of the skin. The average aggregate relative biological effectiveness (RBE) of ^{3}H from orthovoltage X-rays in six studies using chronic γ-ray reference was 2.19 (95% CI: 2.04–2.33) compared with 1.17 (95% CI: 0.96–1.39) for three studies using chronic X-ray reference groups.[427]

EXPOSURE

Tritium exposure is common in the nuclear energy and weapons industries. Fission of a ^{235}U nucleus by a thermal neutron releases a ^{3}H nucleus (triton) once in 10^{4} fissions.[428] Heavy water (D_2O) moderated nuclear reactors also produce tritium following irradiation of deuterium (^{2}H nucleus) by neutrons. The design of some nuclear weapons requires a constant source of ^{3}H manufactured by the process of neutron capture in ^{6}Li nuclear reactor rods. Fusion nuclear reactors use ^{3}H as fuel. Other ^{3}H uses include the manufacture of radionuclide-labeled materials in medicine, industry, and research primarily to examine biologically important chemicals. Tritium is a common metabolic tracer and constituent of luminous paint (wrist watches, gunsights, emergency exit signs).

ENVIRONMENTAL FATE

Tritium is a ubiquitous component of the environment including biological systems; tritiated water is highly mobile in the environment. ^{3}H is a natural contaminant of water that is more common since discharge of tritium-contaminated waste from nuclear fuel reprocessing plants including tritiated water, tritiated hydrogen gas, and organically bound ^{3}H during the nuclear age. Although ^{3}H discharges to the environment are potentially large, the weak β energy and short half-lives limit radiation exposure for the general population. The estimated cosmogenic tritium exposure is 0.01 μSv compared with <10 μSv for the use of radio-luminous watches.[429]

DOSE-RESPONSE

The lack of ^{3}H-specific dose data, low doses, and limited power complicate the correlation of dose to the risk of adverse effects in occupational and environmental settings.[428]

TOXICOKINETICS

^{3}H penetrates the skin, lungs, and gastrointestinal tract as tritiated water or in vapor form. The body does not absorb ^{3}H in the elemental form. In a study of six workers chronically exposed to tritium, the average contribution of organically bound tritium to the total body water dose was 6.9 ± 3.1% (range, 4.7–9.9%).[430] As tritiated water, ^{3}H distributes widely and rapidly (i.e., few hours) throughout the body with a biological half-life of 12 days; however, urinary excretion of a small fraction of this radionuclide occurs at a much slower rate. A few days after the exposure of four workers during the cleanup of tritiated water, the biological half-life of tritium ranged from 7.5–9 days.[144]

CLINICAL RESPONSE

Health effects from single-dose exposure to ^{3}H have not been reported, but repeated exposure to ^{3}H has been associated with the development of aplastic anemia.[25]

DOSIMETRY

A concentration of 1 μCi/L indicates an integrated whole-body dose of 10 mrem.[25] Special survey equipment is necessary to detect the presence of the weak β-particles emitted by ^{3}H. Freshly voided samples must be collected immediately so that the amount of internal contamination can be measured.

TREATMENT

Forced diuresis guided by the analysis of daily urine samples for tritium is the recommended therapy for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. overexposure based on rodent studies; however, fluid and electrolyte balance must be monitored closely. In a study of $B6C3F_1$ female mice injected intraperitoneally with 811 MBq tritiated water, all injected mice receiving diuretics (furosemide 2 hours and 24 hours postexposure) and excess water survived, whereas 80% of controls died the first month postexposure.[431] The estimated final committed radiation dose was 60% lower in treated mice than controls.

URANIUM

HISTORY

The German apothecary Martin Heinrich Klaproth discovered uranium in 1789. Christian Gottlieb Gmelin conducted animal experiments with uranium compounds (e.g., chloride, nitrate) in 1824, 17 years prior to uranium purification. Henri Becquerel discovered uranium radioactivity in 1896 following his experiments with potassium uranyl sulfate. Before the discovery of insulin in the 1920s, some clinicians administered uranyl nitrate for the treatment of diabetes mellitus in daily doses up to 5.8 g.[432] In 1917, Wilcox reported no significant pathology following the chronic administration of 200 mg uranium nitrate daily.[433] During the 1950s, soluble uranyl nitrate was injected into comatose, terminally ill patients as a potential therapy for malignancies.[434]

PHYSICOCHEMICAL PROPERTIES

Uranium is a highly dense member of the actinide series that decays primarily by α-particle emission and lower energy γ-emissions; this element has the highest atomic mass and the second highest density of all naturally occurring elements. Uranium does not exist in the metallic form naturally because of rapid oxidation of the metallic surface to UO_2. Natural uranium exists in five oxidation states (+2 to +6) with the tetravalent (uraninite, pitchblende) and hexavalent (uranyl oxides, carbonates, phosphates, vanadates) predominating. Hexavalent uranium typically forms more systemically toxic, soluble compounds than the relatively less soluble tetravalent uranium compounds, whereas insoluble uranium compounds are potentially slightly more toxic to the lungs. Table 41.27 lists examples of uranium compounds with three relative water solubilities used in ICRP modeling.

There are 16 uranium isotopes; all of these isotopes are radioactive; however, exposure to ionizing radiation from natural uranium isotopes is very low because of the extremely long physical half-lives. Metallic uranium powder can spontaneously ignite at room temperature in the presence of oxygen, air, and water; prevention of auto-ignition requires storage in open containers under machine oil or water. At 200–400°C, uranium powder may self-ignite in atmospheres of CO_2 and N_2. Table 41.28 lists the identifying characteristics and physical properties of uranium and stable uranium compounds.

TABLE 41.27. Relative water solubility of several uranium compounds.

Water Solubility (Dissolution Rate)	Compound
Slow (S)	Uranium dioxide, uranium octaoxide
Medium (M)	Uranium tetrafluoride, uranium trioxide
Fast (F)	Uranium hexafluoride, uranyl fluoride, uranium tetrachloride, uranyl nitrate hexahydrate

The typical specific radioactivity of natural uranium is relatively low (i.e., 0.68 μCi/g) due to the very long physical half-life of natural uranium isotopes; consequently, natural uranium produces very little radioactivity/mass of uranium. As listed in Table 41.29, natural uranium consists primarily of ^{238}U. The specific activity of natural uranium increases as the relative abundance of the more rapidly decaying ^{234}U and ^{235}U increases. Enriched uranium required for nuclear reactors contains greater ^{235}U concentrations (i.e., 3–5%, low-enriched) than natural uranium, whereas enriched uranium in nuclear weapons may contain 97.3% ^{235}U (high-enriched). Depleted uranium contains less ^{234}U and ^{235}U, resulting in relatively lower radioactivity (specific activity, 0.33 μCi/g) than natural uranium. Consequently, adverse health effects following depleted uranium exposure result from chemical effects rather than radioactivity. The chemical reactions of all isotopes and isotopic mixtures of uranium are identical regardless of the specific activity (e.g., enrichment).

Figures 41.2 and 41.5 display the principal decay schemes of ^{238}U and ^{235}U, respectively. Table 41.29 lists the occurrence and radioactive properties of the three natural uranium isotopes; these isotopes are primarily α-emitters. The important uranium valences for biological systems are the primarily water-insoluble tetravalent uranium compounds and the frequently water-soluble hexavalent uranium compounds (e.g., uranyl, UO_2^{2+}). Tetravalent uranium usually oxidizes to the more soluble hexavalent form in the body with the subsequent formation of the uranyl ion. Uranium trioxide is water-insoluble; however, this compound

is highly soluble in tissue. The body converts some tetravalent compounds into more soluble hexavalent uranyl compounds. Uranium hexafluoride hydrolyzes rapidly in water. Uranium combines with bicarbonates (60%), transferrin (40%), and small amounts of citrates in the blood.[436]

Depleted uranium used in armor and munitions is ~40% less radioactive than natural U; however, depleted and natural uranium have similar chemical properties and nonradiation toxicity. Table 41.30 lists the physical characteristics of depleted and natural uranium.

EXPOSURE

Production Processes

Uranium mining and milling involve extraction of the uranium ore from underground or open-pit mines, crushing and grinding of the raw ore, chemical leaching, and precipitation of uranium as "yellowcake" from the leachate. Of the over 100 uranium ores, commercial uranium ores (e.g., autunite, pitchblende, carnotite, torbernite) usually contain >1,000 ppm uranium and typically occur in sandstone formations. Extraction of the uranium ore involves either acid or alkali leaching in the presence of the oxidizer, $NaClO_3$. Yellowcake (ammonium diuranate) is the purified precipitate of the leached liquor. Uranium hexafluoride is formed after solvent extraction, denitration, reduction, and the addition of hydrofluoric acid; the subsequent reduction of uranium hexafluoride with magnesium or calcium produces uranium metal. Niobium ores are a potential source of ^{238}U exposure.

Enrichment is the industrial process that increases the percentage of the more radioactive ^{235}U in uranium ore. Nuclear reactors except pressurized heavy-water reactors use uranium enriched from <1% ^{235}U in natural uranium to 2–3% ^{235}U; certain special reactors and nuclear bombs require uranium with ^{235}U concentrations exceeding 90%.

Uses

The primary use of uranium (uranium dioxide) is as a fuel for nuclear reactors; the primary use of depleted uranium is as a component of modern conventional weapons systems. As of 2021, nuclear reactors produced ~19.6% and ~14.8% of the electricity in the United States and the United Kingdom, respectively.[437] Types of uranium fuel used in nuclear reactors include: 1) unenriched uranium metal fuel (gas-cooled Magnox reactors), 2) unenriched UO_2 fuel (heavy water-cooled, moderated reactors), 3) low-enriched UO_2 fuel (advanced gas-cooled, graphite-moderated reactors, light water-moderated and cooled reactors), and 4) mixed UO_2–PuO_2 fuel (light-water and fast-breeder reactors). Other uses for uranium include the manufacturing of aircraft stabilizers, inertial orientation devices, gyroscopes, green or yellow glass, and luminous devices.[438] The density and hardness of depleted uranium (i.e., 70% greater than lead) are useful for specialized engineering applications including armor, armor-piercing ammunition, and weapons. Nonmilitary uses for depleted uranium include manufacture of radiation shielding material, X-ray targets, and inertial guidance systems.[439] In contrast to enriched light-water reactor fuels, depleted uranium and natural uranium contain ~0.2% and 0.71% ^{235}U, respectively; therefore, depleted uranium has ~60% of the radioactivity of natural uranium as displayed in Table 41.30.[440] Depleted uranium, a by-product of the enrichment process for nuclear reactors and weapons-grade uranium, usually contains <0.3% ^{235}U. Uranium carbide is a catalyst for ammonia production; uranium dioxide extends the life of the large incandescent lamps in the motion picture industry.

Sources

The abundance of uranium, arsenic, and molybdenum in the soil is similar.[435] Because of the presence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

uranium in soil, air, and water, environmental exposure to uranium is common. *In vitro* studies on uranium solubility in soil indicate the predominant exposure pathway for uranium involves ingestion of soil and groundwater, whereas inhalation of uranium from dust is a relatively minor exposure pathway.[441] In addition to the incorporation of natural uranium, uranium exposure occurs during mining and processing of uranium ore, production of uranium-containing phosphate fertilizers, and contact with uranium-containing waste sites.[442]

ENVIRONMENTAL FATE

Air

The contribution of inhalation to the body burden of natural uranium is minimal, with the average amount of uranium absorbed from air containing ~0.06–0.4 ng/m^3 and ranging from ~0.00003–0.0003 Bq/day, depending on the local sources of uranium emissions.[443] Limited quantitative data on airborne uranium suggest the mean U concentrations are typically <0.1 ng/m^3.[444]

Soil

The crust of the earth contains a mean U concentration of ~2–3 ppm (~1.5–2 pCi/g) uranium composed of the following isotopes: ^{238}U (99%), ^{235}U (0.72%), and ^{234}U (minute),[445] with monazite sands, lignite, and phosphate rock containing substantial uranium concentrations. At a concentration of 2 ppm, a truckload of dirt contains a tablespoon of uranium. Because of the slow decay rate of ^{238}U, the total amount of uranium in the earth remains almost constant. The natural ratio of the two main uranium isotopes, ^{238}U and ^{235}U, in the earth's crust is 137.9:1, whereas the ^{238}U/^{235}U ratio in depleted uranium is about 490:1.

Water

Surface and groundwater typically contain similar uranium concentrations with the ^{238}U/^{234}U ratio varying between different locations.[446] In the United States, geological regions with the highest uranium water concentrations are the Rocky Mountains, Colorado Plateau, and the West Central Platform. Uranium in surface water can disperse over large distances to ponds, rivers, and oceans depending on adsorption and release of uranium from aquatic sediments. Factors determining uranium mobility include oxidation–reduction potential, pH, and sediment characteristics. The groundwater in certain mountainous areas of some countries (e.g., Canada, Finland, Norway, Sweden, United States) contains relatively high uranium concentrations.[438] Some groundwater systems in the western United States and scattered areas of the eastern United States (Connecticut, Maine, North Carolina) contain uranium concentrations exceeding 20 ng/mL.[447] In 14 community drinking-water samples from New York State, the mean uranium concentration was 548 mBq/L (range, 36–2,135 mBq/L).[448] In a German study of 582 public drinking-water samples, the radiation dose from ^{238}U ranged from <0.7–320 mBq/L, with a median of 3.2 mBq/L and a 95th% of 100 mBq/L.[307] Private wells may contain higher uranium concentrations than public water distribution systems, particularly in areas drawing water from geological formations containing metamorphic rock formations (e.g., Brookfield Gneiss, western New England).[445,449] Uranium was the element contributing the smallest total radioactivity to distribution solids contained in drinking-water distribution systems collected during routine fire hydrant flushing in four US states (Illinois, Minnesota, Texas, Wisconsin).[308] Total mean α- and β-radiation from uranium was 6.4 pCi/g compared with 143 pCi/g from radium and 40 pCi/g from thorium. In a study of drinking water from 96 bore wells in Bangalore, India, the mean uranium concentration was 92.42 μg/L (range, 0.136–2,027.5 μg/L), with 39% of the well water exceeding the WHO drinking water guideline (30 μg/L).[450] The very low assimilation efficiencies of higher trophic aquatic organisms result in a decline in uranium concentrations with each successive trophic level.[451,452]

Lifestyle

The daily US uranium intake from food averages ~1–3 μg (1 μg ≅ 5 mBq), with uranium isotopes contributing relatively small amounts to the total radiation doses.[453,454,455] In a study of New York City residents, the total estimated daily intake was 18 mBq/L for ^{234}U, 0.7 mBq/L for ^{235}U, and 16 mBq/L for ^{238}U.[381] Shellfish and root vegetables contain relatively higher uranium concentrations with lesser amounts in cereals, fish, and fresh vegetables. Uranium in drinking water usually contributes negligible amounts of α-radiation to the annual radiation dose from water and air; however, water may sometimes contain relatively high uranium concentrations in certain areas. The uranium concentration in 29 tap and bottled water samples in an Italian study ranged from 0.04–5.86 μg/L.[456] Inhalation is a relatively small source of uranium exposure (i.e., 0.0007–0.007 pCi/day; 0.001–0.01 μg/day) compared with food.[435] The contribution of natural uranium to the radiation dose

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from smoking is relatively small compared with other radionuclides (^{226}Rn, ^{228}Rn, ^{210}Pb).[444]

DOSE-RESPONSE

The uranyl ion disassociates from bicarbonate in the kidney to form ligands with phosphates potentially resulting in the disruption of cellular enzymes in the tubules. Animal studies suggest that this effect occurs at doses of 3 μg uranium/g kidney tissue, whereas other reports suggest that these effects on the kidney may occur at levels between 0.1 and 0.4 μg uranium/g kidney.[457] The disruption of cellular enzymes in the kidney produces glucosuria, proteinuria, aminoaciduria, and enzymuria.[438] Because the kidney clears uranium deposits rapidly, regeneration of the tubules typically begins within a week of exposure to the uranium.[305]

TOXICOKINETICS

Absorption

The absorption of uranium from various exposure routes is usually low, depending primarily on water solubility.

Lungs

Deposition and retention of uranium in the lungs depend on particle size and water solubility with a typical range of <1–5%. Absorption into the blood occurs within days of the deposition of the more soluble uranium compounds (uranyl nitrate hexahydrate, uranyl fluoride, uranium hexafluoride), whereas the less soluble compounds remain in the lungs for weeks (uranium tetrachloride, uranium tetrafluoride, uranium trioxide) or years (uranium dioxide, uranium oxide). The ICRP recommends that the first two groups of uranium compounds be classified as inhalation class D (days) and inhalation class W (weeks), respectively; this agency assigns an absorption factor of 5% for the ingestion of these compounds. In a study of mill workers exposed to airborne uranium, the estimated daily mean uranium absorption was 24 μg (0.34 μg U/kg for 70-kg reference man).[312] Based on fecal uranium excretion and workplace ambient air concentrations, the estimated mean pulmonary uranium absorption was 0.76% (range, 0.4–1.6%).

Gastrointestinal Tract

The gastrointestinal absorption of uranium depends on water solubility, physiochemical characteristics, nutritional status (i.e., iron content), and species; animal and human studies have not demonstrated gender differences in absorption rates. Systemic bioavailability typically ranges from 0.1–2% with a maximum of 6%.[458] A review of controlled experimental human studies and a variety of environmental studies demonstrated the average gastrointestinal uranium uptake in food and fluids averaged 1–1.5% of the total uranium intake with a range up to 5%.[459] In a study of 50 Canadians using analysis of duplicate diet samples by inductively coupled plasma/mass spectrometry to estimate daily U intake, the absorption rate averaged 0.9% with a range of 0.1–6%.[460] Another review of the literature suggested an absorption factor of 1–2% for uranium in the diet.[312] Uranium compounds in the inhalation class Y (years) are assigned an absorption factor (f_1) of 0.2%. The mean uranium absorption calculated for three volunteers living in a uranium milling community with no work experience at the mill was 0.82% (range, 0.6–1%); presumably their uranium exposure was primarily gastrointestinal from food and water.[299]

Skin

Uranium compounds can penetrate the skin, especially uranyl nitrate; this compound diffuses through the skin and accumulates in the intracellular space between the granular and horny layers.[461]

Distribution

Absorbed uranium typically exists in body fluids as uranyl ions $(UO_2)^{2+}$ complexed with anions (e.g., bicarbonate, citrate, transferrin) depending on pH. The typical body burden of uranium in the general population is ~90 μg.[435] The estimated body burden of skeletal uranium in New York City residents was ~2–4.5 μg/kg based on autopsy specimens.[453] Based on autopsy studies of workers exposed to uranium, the skeleton is the main storage depot for uranium, with the uranyl ion replacing calcium in the hydroxyapatite complex of bone crystals; lesser amounts of uranium accumulate in the kidney and small amounts in the liver. The ratio of uranium in the skeleton, liver, and kidney was 63:2.8:1 in an individual occupationally exposed to uranium.[462] In a Japanese study analyzing uranium concentrations in Tokyo residents with α-spectrometry and a fission track method, the mean distribution of the estimated 40 μg-total body uranium burden was the following: muscles, 40%; skeleton, 20%; blood, 10%; lungs, 4%; liver, 1%; and kidney, 0.3%.[463]

Animal studies suggest that ~10–20% of the absorbed uranium dose distributes to the surface of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

bones and bone marrow.[464] The kidney receives ~10% of the absorbed uranium dose. The distribution of uranium migrating from embedded depleted uranium is similar to the long-term accumulation in the kidneys, bones, and liver determined by the 1995 ICRP model for uranium.[465] However, this model provides limited information on the distribution of uranium to less frequently studied sites (e.g., lymph nodes, testicles, brain).[466]

Elimination

In a study of four volunteers on a Metabolic Research Ward, the total daily uranium intake from the diet and drinking water for ^{234}U ranged from 35–65 mBq compared with 24–46 mBq for ^{238}U.[467] Excretion of these two isotopes occurred primarily in the stool, with urinary excretion of ^{234}U and ^{238}U averaging 1.8% and 1.5%, respectively, of the daily intake. Hematological clearance of absorbed uranium is relatively rapid, with ~2/3 of the absorbed dose excreted by the kidneys within 24 hours. The ICRP model indicates the kidney excretes 80% of the absorbed uranium dose during the first day; during the first week, the kidney excretes an additional 17.6% of the absorbed uranium dose.[468] The half-life of uranium in the kidney is 1–6 days, whereas the 2-compartment ICRP model describes uranium loss from bones with half-lives of 20 and 5,000 days. The more soluble uranium compounds (uranium hexafluoride/tetrachloride, uranyl fluoride/nitrate hexahydrate) are distributed more diffusely from the alveoli to the blood (ICRP inhalation Type F, fast dissolution). In contrast, less soluble compounds (uranium tetrafluoride, uranium trioxide) remain in the lung and adjacent lymph nodes for weeks (ICRP Type M, medium dissolution), and relatively insoluble compounds (uranium dioxide, uranium oxide) may remain in the lungs for weeks to years (ICRP Type S, slow dissolution). Hence, elimination of ~2–3% of the absorbed uranium occurs over years. Uranium elimination may be delayed in some situations (e.g., uranium hexafluoride exposure) when pulmonary edema complicates the clinical course.[469] Following UF_4 powder exposure during an occupational accident, urinary uranium excretion during the first 24 hours after the accident was 156.8 μg; peak urinary excretion occurred 60 days after the accident, with normal urine uranium excretion within ~3 years of the accident.[470]

CLINICAL RESPONSE

Uranium has no known metabolic function in animals or humans. Animal studies indicate uranium toxicity from natural and depleted uranium results from chemical-induced renal tubular damage by soluble uranium compounds and respiratory tract injury (e.g., noncancerous alveolar epithelium damage of type II cells) from chronic inhalation of insoluble uranium compounds. Because of the low radioactivity of ^{238}U, the primary health hazard of this isotope results from adverse effects on the renal tubules (e.g., proteinuria, casts, polyuria, oliguria, anuria) rather than radiation-induced damage including cancer;[471,472] however, prolonged exposure to insoluble uranium compounds may produce a slightly increased ionizing radiation risk. Natural, depleted, and enriched uranium share similar chemical toxicities. Relatively insoluble enriched ^{235}U compounds (oxides, hydrides, carbides) produce theoretical risks of pulmonary fibrosis and cancer;[473] however, epidemiological studies have not detected elevated mortality rates from typical occupational and environmental uranium exposures. Evaluation of human data is often complicated by coexposures to other toxins (e.g., crystalline silica, diesel engine exhaust, hydrogen fluoride, radon).

Acute Exposure

Uranium Fluoride Compounds

Uranium hexafluoride decomposes into a severe respiratory and mucous membrane irritant, hydrofluoric acid. Exposure of two workers to a dense cloud of steam, uranium hexafluoride, uranium oxyfluoride, and hydrofluoric acid caused nausea, vomiting, dyspnea, corneal abrasions, and pulmonary edema; however, follow-up 38 years later revealed no uranium deposition and no physical sequelae including normal pulmonary function.[474] The estimated initial lung deposition of soluble natural U was ~40–50 g; the mean duration of exposure was 17 seconds. The acute effects were associated with hydrofluoric acid exposure including the death of two workers from inhaling hydrofluoric acid fumes. Following accidental occupation exposure to uranium tetrafluoride powder, a worker developed anorexia, diarrhea, abdominal pain, and hematuria during the first 6–9 days; however, he recovered without permanent sequelae.[470]

Uranium Acetate

Acute renal failure requiring 2 weeks of hemodialysis, renal tubular acidosis with glucosuria and phosphaturia, rhabdomyolysis, myocarditis, elevated hepatic transaminases with liver dysfunction (INR = 2.5, aPPT = >50), anemia, and paralytic ileus developed

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

after the intentional ingestion of 15 g uranium acetate.[475] Urinary alkalinization and daily $CaNa_2EDTA$ began 16–24 hours after ingestion; chelation continued daily for 5 days without a clinically significant benefit. At 6-month follow-up, he had no evidence of cardiac, liver, or muscle toxicity; however, he was mildly anemic (hemoglobin = 11.8 g/dL) with an incomplete Fanconi syndrome requiring daily sodium bicarbonate.

Environmental Exposure

Mortality studies of populations living near uranium mining and milling operations have not demonstrated statistically significant associations between mortality and uranium exposure. Uranium is a nephrotoxic metal in large doses, primarily affecting the proximal tubules. Some, but not all, cross-sectional studies of exposure to natural uranium-containing drinking water suggest an association between uranium concentrations and elevated biomarkers of proximal renal tubular dysfunction; however, these biomarkers are not typically associated with detectable reduction in renal function (i.e., glomerular filtration) or cancer risks.[476,477] Frequently, the elevated biomarkers remain in the reference range. Consequently, the clinical relevance of the positive findings is unclear. There is little evidence that uranium exposure causes neurological or cardiovascular toxicity in humans following occupational uranium exposure.

Community-based studies in Canada, Finland, and Sweden suggest some risk of adverse effects from chronic exposure to elevated uranium concentrations in drinking water, manifested by elevated biomarkers of proximal tubule damage (e.g., urinary glucose, calcium, β_2-microglobulin, retinol binding protein).[478] In a Canadian study of residents in Nova Scotia exposed to high uranium concentrations in drinking water and food (daily range, 3–570 μg) and controls (daily range, <1–20 μg), daily uranium intake correlated with some biomarkers of proximal tubule injury (urine glucose, β_2-microglobulin), but not with enzyme activity (*N*-acetyl-*β*-D-glucosaminidase) or glomerular integrity (urine protein).[479] In a Finnish study of 325 individuals from areas with high uranium concentrations in drinking water, the median daily uranium intake was 39 μg (range, <1–4,128 μg). Urinary uranium concentrations correlated with excretion of some urinary biomarkers of proximal tubular function (fractional calcium, phosphate), but not others (β_2-microglobulin, glucose) based on analysis of spot urine samples.[480] A majority (i.e., 65%) of the β_2-microglobulin results were below the limit of detection. They did not observe a relationship between uranium exposure and urinary albumin (glomerular integrity) or creatinine clearance (glomerular filtration). Epidemiology studies typically do not demonstrate an association between chronic environmental uranium exposure and clinically apparent renal dysfunction or renal failure.[478]

Epidemiological studies of environmental uranium exposure and glomerular filtration rates are inconsistent. Follow-up studies of Gulf War veterans exposed to depleted uranium[481] and a cross-sectional study of 193 Finnish residents chronically exposed to elevated uranium concentrations in well water (median = 25 μg/L; interquartile range, 5–148 μ/L; maximum, 1,500 μ/L)[482] did not detect reduced creatinine clearance in the exposed groups as measured by overnight and 24-hour urine samples. The former study was unadjusted and underpowered due to small sample size, whereas the latter study used linear regression modeling adjusted for age, sex, body mass index, smoking, and analgesic use but not diabetes. In this latter study, biomarkers of proximal renal tubular function and renal toxicity did not correlate to well-water or urine U concentrations. An ecological study suggested an association between serum creatinine and residents living within 2 miles of a uranium processing plant, when compared with residents living over 2 miles from the facility.[483] A case report of seven family members (two adults, five children) exposed for 5 years to drinking water containing markedly elevated uranium concentrations (e.g., 1,166 μg/L) demonstrated only subclinical renal effects in one child (↑β_2-microglobulin) that resolved within 3 months.[449]

Occupational Exposure

Uranium Workers

Occupational cohort studies do not indicate an increased risk of kidney-related mortality among uranium workers; however, some occupational studies suggest chronic uranium exposure may produce proximal renal tubular damage based on elevated urinary biomarkers (e.g., calcium, glucose, low-molecular-weight proteins).[478,484] In a mortality study of 1,484 men employed in seven uranium mills in the Colorado Plateau for at least 1 year on or after 1940, deaths from all causes and all cancers, including renal cancer, were less than expected based on US mortality rates.[485] Although the study detected nonsignificant increases in mortality from lung cancer and chronic renal disease, mortality was not related to duration of employment; there was no direct measure of cumulative uranium exposure. Smoking data and individual exposure assessments were not available. In a review of eight cohort studies

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

on the mortality of workers at uranium processing facilities, the standardized mortality ratio (SMR) for chronic nephritis ranged from 0.67–1.88, with wide confidence intervals and a similar distribution of the SMR around 1.[478] A cross-sectional study of uranium workers demonstrated a mild increase in the urinary clearance of β_2-microglobulin and amino acids compared with a control group without uranium exposure. However, none of the workers demonstrated elevated urinary β_2-microglobulin, amino acids, or creatinine when compared with the upper limits of normal for populations of workers.[486]

Follow-up studies of uranium millworkers suggested an inverse association between uranium exposure and serum creatinine.[486] In a cross-sectional study of 684 current and former Korean lead workers, higher log transformed urine concentrations in adjusted linear regression models were associated with lower measured creatinine clearance in models using creatinine to adjust urine concentrations; however, the association was no longer significant when using an absolute measure of creatinine (μg/4-hour urine collection).[487] This study suggests some association between urine uranium and kidney outcomes may result from statistical rather than nephrotoxic effects secondary to the use of urine creatinine in both exposure and outcome metrics.

Military Uses (Depleted Uranium)

Most studies of Gulf War veterans with embedded fragments containing depleted uranium have not detected clinically significant liver, kidney, bone, hematological, nervous, and reproductive (neuroendocrine hormone concentrations, sperm counts) abnormalities. However, some follow-up studies on military veterans suggest adverse proximal renal tubular effects (e.g., ↑ urinary β_2-microglobulin, retinol binding protein). A cross-sectional study of 29 Gulf War veterans with retained metal shrapnel fragments containing depleted uranium demonstrated increased urinary uranium concentrations 7 years after exposure.[481] No adverse renal effects were detected in this study as measured by clinical laboratory values, psychiatric evaluation, and neurocognitive assessment. An 18-year follow-up study of 80 veterans with embedded depleted uranium fragments from Gulf War I demonstrated continued uranium excretion (range, 0.006–1.88 μg uranium/g creatinine); however, there was no evidence of elevated biomarkers of renal tubular dysfunction, glomerular damage (integrity, glomerular filtration), or bone resorption.[488] Comparison of the high-urine uranium group (mean = 5.997 ± 10.773 μg/g creatinine, $n = 12$) and the low-U exposure group (mean = 0.009 ± 0.016 μg/g creatinine, $n = 25$) did not demonstrate any significant differences between the two groups in spirometry, pulmonary symptoms, serum chemistry, hematological parameters, or biomarkers of renal dysfunction.[489] In a 12-year follow-up study of 32 veterans with retained fragments of depleted uranium, uranium concentrations in 24-hour urine collections ranged from 0.001–41.8 μg/g creatinine.[490] There were no detectable abnormalities in blood chemistries, complete blood count, renal glomerular and tubular function, neuropsychological measures, or semen quality when comparing high exposure (≥10 μg/g creatinine) and low exposure (<10 μg/g creatinine) groups. A 25-year follow-up of this cohort of military veterans continued to demonstrate an absence of U-related health effects in known target organs of uranium toxicity, including normal renal function.[491] Similarly, a 20-year follow-up of exposed veterans did not demonstrate any differences in self-reported respiratory symptoms, prevalence of low-dose chest computed tomography abnormalities, or mean pulmonary function values, when comparing the low- and high-exposure groups based on 24-hour urine total U concentrations.[492]

Formation of a fine aerosol of mostly (i.e., >65%) insoluble uranium oxides occurs when a depleted uranium round strikes a target. In the Capstone Depleted Uranium (DU) Aerosol Characterization and Risk Assessment Study, all vehicle configurations and modeled exposure times with the exception of unventilated Abrams tank perforated through DU armor predicted radiation doses below the US occupational limits.[493] Risk analysis indicates leukemia and birth defect risks following exposure to depleted uranium during wartime uses are too small to observe.[494]

Carcinogenesis

The International Agency for Research on Cancer (IARC) considers the evidence for carcinogenicity of mixtures of uranium isotopes (natural, enriched, depleted) in humans limited with sufficient evidence of carcinogenicity in experimental animals.[348]

Occupational Exposure

The risk of developing cancer following exposure to natural uranium or ^{238}U is small because of the low radioactivity of these compounds and the extremely long physical half-lives. The risk of cancer is greater following internal exposure to enriched uranium, including workers involved with nuclear fuel cycles and uranium miners exposed to radon and uranium dust. Potentially, these workers are exposed to increased risk of malignancies of the lung, larynx, and lymphatic and hematopoietic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tissues; however, the findings are inconsistent as a result of inadequate measures of radiation dose, potential concomitant exposure to chemicals, confounding by smoking, age-related effects, and ascertainment bias complicate the interpretation of epidemiological studies of workers exposed to uranium.[495]

Some studies of uranium miners demonstrated an increased incidence of oat cell and squamous cell carcinomas of the lungs,[496,497] with a lower 95% confidence limit in one study of 14.4.[498] In a population-based, case-control study of 94 incident cases of lung cancer in Navajo males identified after the closing of the local uranium mine and followed for 25 years, the relative risk of developing lung cancer in a Navajo uranium miner was 28.6 (95% CI: 13.2–61.7) compared with Navajo males without a history of working in the uranium mine.[499] The relative risk did moderate slightly over time. The prevalence of smoking among Navajo males is low and smoking did not account for the strong relationship between lung cancer and uranium mining. In a cohort mortality study of 6,409 uranium workers followed for a mean of 37 years, there was little evidence of a dose-response trend for any cancer evaluated, except intestinal cancer (excess relative risk = 1.5/100 μGy; 95% CI: 0.12–1.42/100 μGy).[500] The standardized mortality rates were elevated for lung cancer in hourly (but not salaried) male workers and lymphohematopoietic cancer in salaried men; however, there was no relationship of the SMRs to dose. Studies of uranium mill workers demonstrated a slight excess of cancers of the lymphatic and hematopoietic tissue, with a relative risk up to ~2.[501,502] A long-term mortality study of nuclear-processing plant workers exposed to low doses of internal α-radiation and external radiation demonstrated a 20% increase in the standardized mortality rate (SMR 95% CI: 1.04–1.38).[503] Other studies of uranium dust exposure and lung cancer mortality among workers employed at uranium processing plants have not demonstrated dose-related effects of uranium exposure and lung cancer.[504] Typically, the exposure to radon in these plants is much lower than uranium miners. Although separation of the effect of exposure to uranium from the effect of confounding variables (e.g., radon, smoking, silica, dusts, and diesel engine exhaust fumes) is difficult, there is insufficient evidence to support a causal relationship between cancer and exposure to natural uranium.[305] Nephrotoxicity from the chemical effects of uranium would be expected to appear before the onset of cancer.

Environmental Exposure

No clear evidence links oral environmental uranium exposure to human cancer. In a case cohort study of 61 bladder cancer and 51 kidney cancer cases, a substantially increased risk of these 2 cancers was not associated with cumulative exposure to elevated well-water uranium concentrations; however, the study had relatively low statistical power.[329] In an ecological study of county residents living near the Grants Uranium Mill operated from 1958–1990 with follow-up through 2004, there was no consistent evidence that operation of uranium mills and mines adversely affected cancer incidence or mortality of county residents.[505] Lung cancer mortality and incidence were significantly increased among men (SMR = 1.11; 95% CI: 1.02–1.21; SIR 1.40, 95% CI: 1.18–1.64) but not women (SMR = 0.97, 95% CI: 0.85–1.10; SIR 1.01, 95% CI: 0.78–1.29). The authors attributed the slight excess mortality and incidence of men with lung cancer to coexposures (i.e., radon gas and decay products, smoking) and socioeconomic factors.

Reproductive Abnormalities

Although a review suggested the possibility of an association between depleted uranium exposure and teratogenicity,[506] the data have not been evaluated in peer-reviewed journals. Few data are available to correlate uranium exposure with developmental abnormalities in humans or animals following inhalation exposures of any duration including alteration of neuroendocrine function (follicle stimulating hormone, luteinizing hormone, testosterone);[507] consequently, a causal relationship between depleted uranium and developmental toxicity (e.g., birth defects) has not been established. Animal studies indicate uranium can cross the placenta after parenteral administration.

DIAGNOSTIC TESTING

Conversion Factors

1 μg (natural uranium) = ~0.67 pCi = 24.8 mBq
1 μg/L = 4.2 nmol/L (^{238}U = 238.03 g/mol)

Analytical Methods

Uranium is a ubiquitous element commonly present in food and drinking water. Analytical techniques for quantitating uranium in medical and environmental samples include inductively coupled plasma/mass spectrometry (ICP/MS; LOD, 0.1 μg/L) and inductively coupled plasma/atomic emission spectrometry (ICP/AES; LOD, 0.2 μg/L). Although these two methods are sufficient to quantitate total uranium concentrations in biological media, determination of the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

type of uranium exposure (e.g., natural uranium, NU; enriched uranium, EU; depleted uranium, DU) requires isotopic analysis with enhanced analytical sensitivities. In natural uranium, $^{235}U/^{238}U$ is 0.00725 with little variation (i.e., ~0.1%), whereas $^{234}U/^{238}U$ is much more variable. During the enrichment process, the $^{235}U/^{238}U$ and $^{234}U/^{238}U$ increases substantially compared with natural uranium. These two ratios are substantially lower in depleted uranium than natural uranium.[508]

The most precise techniques for determining uranium isotope ratios include inductively coupled plasma/mass spectrometry (ICP/MS),[509] multicollector/inductively coupled plasma/mass spectrometry (MC/ICP/MS), and thermal ionization/mass spectroscopy (TI/MS). Typically, health physicists use magnetic sector field/inductively coupled plasma/mass spectrometry (SF/ICP/MS) because of less stringent precision requirements;[510,511] however, polyatomic interferences and low sensitivity for ultra-low isotope concentrations limit results. The use of SF/ICP/MS with a high-efficiency nebulizer (Apex PFA microflow) coupled with a membrane desolvating nebulizer system (Aridus II™) improves precision, accuracy, and LOD.[512] α-Spectrometry allows the determination of uranium in water and food;[467] however, the low specific activity of natural uranium produced highly variable recovery.[513]

Biomarkers

In the Fourth National Report on Human Exposure to Environmental Chemicals (NHANES IV), the geometric mean uranium concentration in urine samples from US residents (≥6 years) was 0.007 µg/L (95% CI: 0.006–0.008 µg/L) with an upper 95th percentile of 0.036 µg/L (95% CI: 0.029–0.044 µg/L).[514] The clearance of uranium from the body is rapid; consequently, urine uranium concentrations of >100 µg/L indicate recent or current uranium exposure. Urinary uranium concentrations of <40 µg/L suggest past or typical background uranium exposure.

Bone is a repository for absorbed uranium. In a study of seven Canadian cities, the geometric mean U concentration in ashed human bones from these cities ranged from 2.5 ± 1.4–88.7 ± 1.4 µg/kg.[515] The median of all samples in the Canadian study and a collection of ashed bone samples from the 1990s were similar (i.e., 6.0 µg/kg and 6.8 µg/kg, respectively).[516] In a 7-year follow-up study of 29 veterans with retained, depleted uranium shrapnel fragments, the urinary uranium in the veterans ranged from 0.01–30.7 µg/g creatinine compared with 0.01–0.05 µg/g creatinine in 38 unexposed veterans.[481] In a study of 579 Iraq and Afghanistan veterans monitored through the Veteran's Administration Embedded Fragment Registry, 55% of the veterans had urine uranium concentrations within the reference range, as measured by high-resolution/inductively coupled plasma/mass spectrometry at the time of analysis.[517] Most of the veterans (i.e., 79%) served in Iraq with ~20% sustaining injuries in 2004. The vast majority of veterans submitted urine specimens <10 years after injury. Elevation of dicentric and sister chromatid exchanges in the blood lymphocyte cultures from workers exposed to both soluble and insoluble uranium compounds suggests genotoxicity related to uranium exposure.[518]

HEALTH SURVEILLANCE

Risk Assessment

The intermediate-duration (15–364 days) inhalation minimum risk level (MRL) for insoluble uranium compounds is 2 µg/m^3 based on mild renal tubular changes in dogs exposed to ≥8.2 mg U/m^3 for 5 weeks,[435] whereas the intermediate-duration MRL for soluble uranium compounds is 0.1 µg/m^3 based on mild renal tubular changes (LOAEL) in rats following exposure to 0.15 mg U/m^3. The chronic-duration (>364 days) inhalation MRL for soluble uranium compounds is 0.04 µg/m^3 based on mild renal tubular atrophy in dogs exposed to 0.2 mg U/m^3 for 33 hours/week for 1 year.

The acute-duration (≤15 days) oral MRL is 2 µg U/day for soluble uranium compounds based on a benchmark dose concentration at the 95% lower confidence limit on a 5% response ($BMDL_{05}$) of 0.20 mg U/kg/day for cleft palate in mice with an uncertainty factor of 100. The intermediate-duration oral MRL for soluble uranium compounds is 0.2 µg/day based on a LOAEL value of 60 µg U/kg/day for renal effects in rats with an uncertainty factor of 300.[519] Current animal data suggest a chronic-duration MRL higher than the intermediate-duration value; assuming adequate renal repair processes at low doses, the intermediate-duration oral MRL may be protective for chronic exposures.[435]

Environmental Monitoring

Current human data do not provide a clear no-effect concentration for uranium. The relationship between uranium effects and drinking-water concentrations is complex, with a lack of reported adverse effects following uranium exposures approaching 100 µg/L in drinking water. Recommendations for the limit of natural isotopes in drinking water are based on the nephrotoxicity of natural uranium isotopes at a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 41.31. Regulations and guidelines for exposure to uranium and uranium compounds.

Exposure Limit	Value
OSHA	
PEL–TWA (8 hour)	
Uranium, soluble compounds	50 μg/m^3
Insoluble compounds	250 μg/m^3
NIOSH	
REL–TWA (10 hour)	
Metallic/insoluble compounds	200 μg/m^3
Soluble compounds	50 μg/m^3
REL–STEL (15 minutes) – metallic/insoluble	600 μg/m^3
IDLH – metallic, insoluble, soluble compounds	10,000 μg/m^3
ACGIH	
TLV–TWA (8 hour) – soluble/insoluble	200 μg/m^3
STEL (15-minute TWA) – soluble/insoluble	600 μg/m^3
US FDA	
Bottled water allowable limit	30 μg/L
US EPA reference dose	
RfD (chronic oral exposure)	3 μg/kg/day
Maximum contaminate level (MCL)	30 μg/L
US Federal Drinking Water Guidelines	
World Health Organization (WHO)	
Provisional Drinking Water Guideline	0.015 mg/L
Tolerable daily intake (TDI)	0.6 μg/kg/day
ATSDR minimum risk level (MRL as uranium)	
Acute oral	
Soluble compounds	2 μg/kg/day
Intermediate oral	
Soluble compounds	0.2 μg/kg/day
Intermediate inhalation	
Insoluble compounds	2 μg/kg/day
Soluble compounds	0.1 μg/kg/day
Chronic inhalation	0.04 μg/kg/day

level of 100 μg/L.[312] The provisional WHO guideline for uranium in drinking water is 30 μg/L using the lower confidence limit of 637 μg/day (95% CI: 637–1,646 μg/day) from the Kurttio study[482] as the NOAEL.[520] Applying an uncertainty factor of 10 for intraspecies differences and a default daily water intake of 2 L resulted in a guideline value of 30 μg/L. The US Nuclear Regulatory Commission recommends weekly 10 mg soluble uranium limits to prevent chemical toxicity. The short-term Threshold Limit Value for uranium in air is 0.2 mg uranium/m^3 for soluble and insoluble compounds. The EPA guidelines assign an occupational ALI for ingestion of the natural uranium isotopes of 5×10^5 Bq based on a fraction uptake (f_1) of 0.05 (Table 41.31).

Biological Monitoring

Urine and blood are good biomarkers for the surveillance of individuals exposed to depleted uranium. The ACGIH BEI for uranium in urine at the end of the shift is 200 μg/L when measured within at least 60 days after uranium exposure; this value was developed to avoid kidney injury and hematopoietic abnormalities (e.g., leukemia). Interpretation of urine samples collected prior to 60 days after exposure may not reflect steady-state uranium urine concentrations because of the relatively long uranium half-life. Although 24-hour creatinine-corrected urine samples are usually more accurate than spot urine samples, the latter correlates reasonably well to the former. In a study of 22 DU-unexposed and 29 DU-exposed veterans, the mean and median uranium concentrations were similar in the two groups.[521] The creatinine-corrected spot and 24-hour urine uranium concentrations correlated well ($R^2 = 0.97$) when the two groups were combined and the urine uranium concentration was ≥0.05 μg/g creatinine. The correlation decreased ($R^2 = 0.44$) when the uranium concentration was low (<0.05 μg/g creatinine). The spot sample without adjustment for volume, concentration, or creatinine correlated relatively poorly with the adjusted 24-hour urine uranium concentration, particularly at low urinary uranium concentrations (i.e., <0.05 μg/g creatinine). The US Nuclear Regulatory Commission action level for urinary uranium is 15 μg/L.

In a study of German peacekeeping personnel and residents of the Kosovo region, the daily uranium excretion rates were similar in both study groups.[522] The geometric mean of daily uranium excretion was 13.9 ng and 12.8 ng, respectively. The intersubject variation in uranium excretion was relatively high (i.e., geometric standard deviation = 2.17 ng and 2.60 ng, respectively). Elevation of the $^{238}U/^{235}U$ ratio substantially above the natural ratio of 137.9:1 indicates past exposure to depleted uranium. Spot urine samples were analyzed for the $^{238}U/^{235}U$ ratio in the following four groups of British military personnel serving in Iraq: 1) combat ($n = 199$), 2) noncombat ($n = 96$), 3) medical ($n = 22$), and 4) "clean-up" ($n = 24$).[523] There was no statistically significant difference in the mean $^{238}U/^{235}U$ ratio between the four groups. In a study of 732 military personnel on active duty in areas without current conflicts, the adjusted uranium concentration in urine samples ranged up to 556 ng/g creatinine with a median value of 2.7 ng/g creatinine and a 95% upper percentile of 142 ng/g creatinine.[524] Isotope ratio measurements indicated a natural isotope signature without evidence of depleted uranium. Removal of workers from uranium work usually results in the rapid return of urine uranium levels to normal reference values.[525]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

In a study of 35 Gulf War I veterans exposed to depleted uranium during combat, the urine uranium concentrations ranged from 0.001–60 μg/g creatinine 16 years after exposure.[507] Although there was a trend to higher urine β_2 microglobulin and retinol-binding protein when the cohort was stratified into high and low exposure based on urine uranium, there were no statistically significant differences between these two groups. Elevated urine uranium and isotopic ratios are unlikely in military personnel without retained depleted uranium fragments.[526]

TREATMENT

Chelation

Uranium is primarily a chemical toxin because the half-lives of uranium isotopes are extremely long. Some authors recommend DTPA as a single dose within 4 hours of exposure to highly enriched uranium (~8% ^{235}U and ^{234}U) as a reasonable method to reduce the potential radiation hazard, with further therapy depending on an assessment of the absorbed uranium dose and the amount of continuing absorption from uranium deposition sites.[469] However, the administration of chelating agents is usually not recommended because of concern that the DTPA-uranium complex may cause nephrotoxicity and the lack of efficacy in human case reports, particularly when administered after the first 4 hours after exposure.[527] Additionally, DTPA chelates important essential elements (calcium, magnesium, manganese, zinc). The IND agreement for DTPA does not include approval by the US Food and Drug Administration for administration following uranium exposure; therefore, the use of DTPA in this setting requires special permission. The use of calcium DTPA and calcium disodium EDTA did not significantly increase the renal excretion of uranium or improve the clinical course following the ingestion of 15 g uranium acetate; initial chelation began 16–24 hours after ingestion.[475]

Although initial studies in mice suggested that the immediate administration of Tiron (sodium catechol sulfate or sodium 4,5-dihydroxybenzene-1,3-disulfonate, CAS RN: 149-45-1) reduced the LD_{50} of uranyl acetate,[528] subsequent rodent studies did not confirm the efficacy of Tiron or DTPA as an effective chelating agent for reducing renal toxicity following an absorbed soluble uranium dose of an order of magnitude above the permitted daily limit of 2.5 mg uranium.[529,530] In mice, administration of Tiron, DTPA, or gallic acid more than 4 hours after subcutaneous injection of uranyl acetate did not alter uranium excretion or reduce uranium tissue concentrations.[531]

Urinary Alkalinization

Urinary alkalinization following exposure to soluble uranium compounds is an effective method of preventing the dissociation of the uranium-bicarbonate complex that damages the kidney (ATN) by the release of the uranyl ion into renal tissue. The clinical endpoint is a urine pH of 8–8.5 during the first 3 days after exposure. Further administration of sodium bicarbonate depends on renal tubular function.

Supportive Care

Methods to quantify uranium exposure include 24-hour urine collections for direct counting of uranium and *in vivo* counting of the chest for the assessment of inhaled insoluble uranium. Baseline levels should be obtained for creatinine clearance and 24-hour collections for glucose and protein excretion as measures of glomerular function. Assessment of tubular function by quantitation of urinary amino acids, β_2-microglobulin, and enzymes usually requires special research techniques.

Treatment of imbedded fragments of depleted uranium includes removal of particles >1 cm unless the medical risk of removal is greater than the risk of retaining the fragment, evaluation of hepatorenal function, and monitoring urinary uranium. Rapid evaluation techniques to detect uranium fragments include using nitric acid in ultrasonic cleaner and masking agents (sodium citrate, ethylenediaminetetraacetic acid).[532]
